Rotatory Dispersion of Cytochrome *c*

The iron atom in hæm compounds has its six covalences directed toward the six corners of an octahedron; there are four co-planar bonds with the porphyrin nitrogen atoms and one bond on each side of the plane of the porphyrin. The only possible plane of symmetry in such molecules is the plane of the porphyrin; the iron must constitute a centre of asymmetry if one of two requirements is satisfied: (1) different groups are linked to iron on the two sides of the porphyrin plane or (2) groups co-ordinated to iron are also attached to porphyrin side-chains, thus forming chelate rings.

Both these conditions are fulfilled in cytochrome *c*, since the amino-acid composition differs on the two sides of the porphyrin[1], and since the protein is linked to both iron[2] and to porphyrin side-chain[3]. The iron atom of cytochrome *c* should, therefore, contribute to the optical activity of the molecule, unless it is racemized, and racemization is not expected in biological compounds.

It has been observed that the oxidized and reduced forms of *tris*-orthophenanthroline-ruthenium exhibit marked differences in optical rotation, with no change in the organic portion of the molecule[4]. Optical activity due to iron in cytochrome *c* may thus be differentiated from the optical activity due to the protein by looking for a difference in rotation resulting from the gain or loss of an electron.

Sigma cytochrome *c* was purified by passing it through a column of *XR*-64 resin[5]. A 0·5 *M* solution in phosphate buffer (*p*H 6·5) was oxidized with potassium ferricyanide, reduced with hydrogen over platinum, and re-oxidized with ferricyanide. Optical measurements were made in a 0·5 cm. cell at 26° with a Rudolf polarimeter, using a zirconium light source and a Beckman monochromator. Fig. 1 shows rotatory dispersion curves for the oxidized and reduced forms; the curve obtained by oxidation of the reduced form is identical with the curve for the solution prior to reduction.

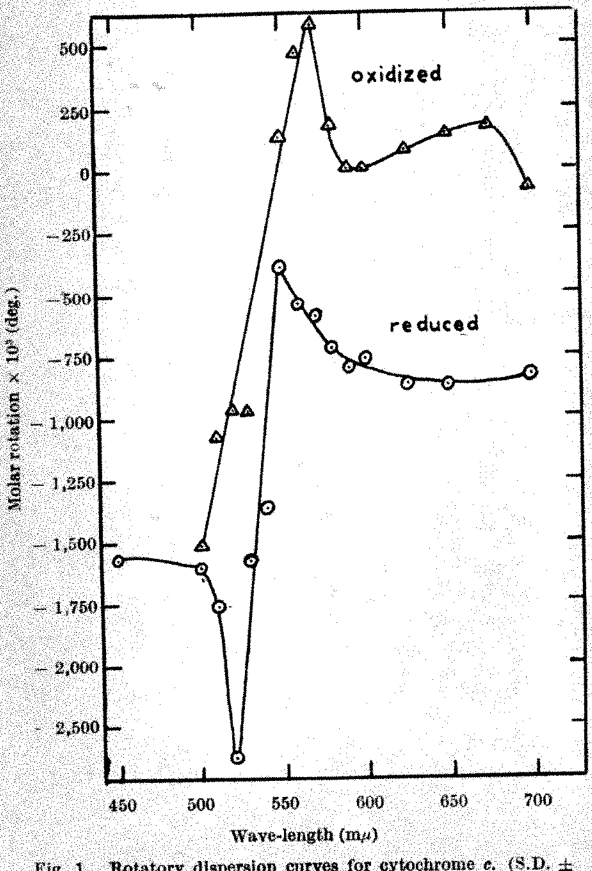

Fig. 1. Rotatory dispersion curves for cytochrome *c*. (S.D. ± 50 × 10⁻³ deg.)

Both oxidized and reduced cytochrome *c* show 'anomalous' dispersion in the region of 550 mμ, where the greatest difference exists in the spectra of the two forms[6]. The absorption in this region probably involves the absorption of the iron–nitrogen bonds; the 'anomalous' dispersion is another indication that the iron is asymmetric.

Similar investigations are being made for other biological porphyrin compounds.

Isolation of a Glycine-Carbohydrate Residue from Muscle Collagen

One of a group of related, macromolecular substances composed of an amino-acid linked to a polysaccharide has been isolated and partially characterized. This group of substances, obtained by means of proteolysis of muscle collagen by carboxypeptidase and subsequent electrophoresis of the non-dialysable fraction, suggests the existence of a polysaccharide residue linked to the C-terminal amino-acid.

Collagen was prepared from rat muscle by a combination of the methods described by Neuberger *et al.*[1] and by Fitch *et al.*[2], employed in the order stated. The collagen preparation used in these experiments was obtained from rats which had been injected intraperitoneally with eight doses of glycine-2-^{14}C (total counts per min. injected, 6·35 × 10⁶; specific carbon-14 activity, 1·88 × 10⁷ c.p.m./mgm.). The rats, which were killed 56 hr. after the injection of the last carbon-14 dose, were also used in related studies reported elsewhere[3]. Similar experiments using D-glucose-U-^{14}C will not be described here in detail.

In a typical experiment, 50 mgm. of muscle collagen was incubated at 37° C. for 20 hr. with 4 mgm. of thrice recrystallized carboxypeptidase in the presence of 0·05 *M* phosphate buffer, *p*H 7·8 and 1·2 *M* lithium chloride. At the end of the incubation period trichloracetic acid was added to obtain a final concentration of 5 per cent, and the resulting precipitate was removed by centrifugation. The supernatant solution was extracted several times with ethyl ether. The residue obtained upon evaporation to dryness was taken up in a small volume of water and was dialysed against running tap water for 24 hr. Paper chromatography carried out subsequent to dialysis in the solvent system[4] 2-butanol/90 per cent formic acid/water, 75 : 15 : 10, v/v/v, revealed the presence of six ninhydrin-reactive substances, all of which had migrated from the starting point. In addition, there was found a large immobile fraction (*A*) which, when sprayed with aniline–phthalate reagent[5], formed a brownish-coloured spot. This spot fluoresced with a yellow colour in ultra-violet light and reacted with ninhydrin slowly to form a yellowish spot.

The entire immobile fraction (*A*) was isolated by means of a 'streak' chromatogram, developed in the solvent system mentioned earlier. This fraction was eluted in water at a slightly alkaline *p*H and a small aliquot was hydrolysed with 6 *N* hydrochloric acid in a sealed tube at 100° C. The following amino-acids could be identified in this hydrolysate: lysine, glycine, glutamic acid, alanine, leucine, phenylalanine, valine and serine. The remainder of the eluate was subjected to continuous paper electrophoresis in 0·090 *M* borate buffer, *p*H 7·8, for 24 hr. at 450 V. and 2–3 m.amp. The eluate was dropped on the centre of the paper sheet above tube No. 12 of a series of 22 tubes. (Tube No. 1 was at the anodic side and No. 22 at the cathodic side.) About 63 per cent of the total carbon-14 activity of the eluate was collected in tubes No. 11–16 (*B*), each tube containing 4 ml. The contents of these tubes were combined and rechromatographed by means of continuous paper electrophoresis at *p*H 5·4 in 0·025 *M* acetate buffer using 610 V. and 2–3 m.amp. Under these conditions, the fractions containing carbon-14 activity had migrated significantly toward the anode and were confined largely to three of the 22 tubes (No. 7–9. (*C*)). The combined contents of the three tubes were again subjected to continuous paper electrophoresis in 0·02 *M* phosphate buffer, *p*H 7·8, at 410 V. and 3 m.amp., whereupon, after 48 hr., almost all of the carbon-14 activity was found in four tubes (No. 11–14 (*D*)), each containing 3 ml. of effluent. Since the point of application of the solution to the paper was directly above tube No. 11, there was a slight displacement toward the cathode, as was the case with electrophoresis in borate buffer at *p*H 7·8. The contents of tubes No. 11–14 were pooled, evaporated to dryness *in vacuo* and the resulting residue subjected to reductive cleavage by adding 500 mgm. of lithium borohydride and 50 ml. of tetrahydrofurane to the dry residue. This reaction was carried out at 65° C. for 5 hr.[6].

Finally, the solution was made 6 *N* with respect to hydrochloric acid and hydrolysed in a sealed tube at 100° for 20 hr. after dinitrophenylation. Paper chromatography in the solvent system described by Grassmann *et al.*[7] yielded only one dinitrophenyl derivative, namely, that of ethanolamine. These findings suggest that glycine is the only amino-acid present in the fraction isolated by continuous paper electrophoresis and that the remainder of the molecule is composed of a substance with macromolecular dimensions, presumably a polysaccharide. Electrophoretic studies of the material remaining after lithium borohydride reduction indicate the presence of a positively charged molecule, the positive charge being perhaps due to the amino-group in hexosamine residues. The carbon-14 activities present in the initial sample of collagen and in various derived fractions are shown in Table 1.

Table 1. TOTAL CARBON-14 ACTIVITY IN FRACTIONS ISOLATED

Fraction	Total carbon-14 activity in fraction (c.p.m.)
Muscle collagen	90,100
Immobile fraction (*A*)	26,000
Electrophoresis in borate buffer (*B*) (tubes No. 11–16)	16,553
Electrophoresis in acetate buffer (*C*) (tubes No. 7–9)	2,069
Electrophoresis in phosphate buffer (*D*) (tubes No. 11–14)	563

The findings reported here indicate that the polysaccharide moiety of collagen is indeed linked to certain C-terminal amino-acids and that this polysaccharide–amino-acid complex is split by carboxypeptidase from the polypeptide chain as an intact macromolecule. One such complex was characterized further by demonstrating the presence of a single amino-acid (glycine) by means of reductive cleavage with lithium borohydride.

Incorporation of Disodium *p*-Nitrophenylphosphate in Solid Medium for the Detection of Phosphatase Production by *Micrococcus pyogenes* var. *aureus*

THE production of phosphatase by *Micrococcus pyogenes* var. *aureus* has been demonstrated using a solid medium incorporating phenolphthalein phosphate[1]. The presence of phosphatase has also been correlated with coagulase production[2], which in turn has been shown to be linked with exotoxin production[3]. Therefore it is assumed that all exotoxin-producing staphylococci are coagulase- and phosphatase-positive. The quantitative study of the phosphatase activity of *Micrococcus pyogenes* var. *aureus*[4] has shown that the production of phosphatase can be used as an index to toxin production.

A medium incorporating disodium *p*-nitrophenylphosphate has been devised in this laboratory with the object of using a single medium for the detection of *Micrococcus pyogenes* var. *aureus* in spray-dried milk powders. Preliminary trials have confirmed earlier work that the use of disodium *p*-nitrophenyl phosphate is much superior to other phosphatase substrates.

The medium consists of nutrient agar to which is added a sterile solution of disodium p-nitrophenyl phosphate. This medium is used in the normal way. The streaked Petri dishes are examined after 24-hr. incubation at 37° C. and the presence of phosphatase is indicated by the yellow colour of liberated p-nitrophenol surrounding colonies of *M. pyogenes* var. *aureus*. Positive results are readily discernible after 16–18-hr. incubation.

The incorporation of high concentrations of sodium chloride in the media has only a slightly inhibiting effect on phosphatase production. This effect is less than the inhibition caused by sodium chloride in a medium using phenolphthalein phosphate as substrate[1], probably because of the high sensitivity of the disodium p-nitrophenylphosphate[5].

Investigations are proceeding to determine the optimal level of substrate concentration and to examine the incorporation of inhibiting agents for Gram-negative organisms.

Metabolic Role of Xanthopterin

ALBERT[1] has suggested that xanthopterin would be found in higher amounts in neoplastic tissues than in normal. In anticipation of confirming this by direct experiment, we have analysed for their pterin content, normal kidney tissue of the golden hamster and transplantable neoplasms in the golden hamster, derived from stilbœstrol-induced renal tumours[2]. No xanthopterin could be found. The largest amount of tissue used was 1 gm. of normal tissue and 8 gm. of neoplastic tissue, and the smallest amount of xanthopterin that could be detected by the paper chromatographic technique used was 0·1 μgm.

Xanthopterin has been isolated from human urine[3]. If, however, xanthopterin is present as a tissue metabolite, some of it should be oxidized to leucopterin by xanthine oxidase[4]. This expectation is borne out by the occurrence of leucopterin in the kidney tubules of golden hamsters given massive doses of xanthopterin[5]. An analysis of human urine failed to reveal leucopterin (which would have been found between the origin and 2-amino-4-hydroxypteridine-6-carboxylic acid in the propanol–5 per cent aqueous acetic acid (2 : 1 v/v) solvent system used)[6].

Kalckar *et al.*[7] found that xanthopterin was not present in freshly voided urine, but that a colourless non-fluorescent substance was present which was converted to xanthopterin by air oxidation. Futterman and Silverman[8] found a labile substance in human urine the properties of which resembled an unformylated reduced folic acid, and Blakley[9] has demonstrated that di- and tetra-hydrofolic acids are readily oxidized to xanthopterin.

Slavik *et al.*[10] found xanthopterin in the urine of rats fed tetrahydrofolic acid but showed that the xanthopterin was formed during isolation by the non-enzymic oxidation of tetrahydrofolic acid.

The present burden of evidence is therefore that xanthopterin is absent from mammalian tissues. The biological effects of xanthopterin in mammals should therefore be attributed only to the disturbance of a normal metabolic pathway by an artificially introduced substance.

A fuller account of this work will be published elsewhere in due course.

We wish to thank the Chemical Society for a grant in aid of this investigation, and Prof. A. C. Haddow and the Chester Beatty Research Institute for the supply of normal hamsters and hamsters with tumours.

Chromatographic Separation of Lactalbumin from Human Milk Whey on Calcium Phosphate Columns

ACCORDING to Deutsch[1] and Wegelin[2] bovine and human milk wheys differ to a certain extent in electrophoretic patterns. On the basis of paper electrophoretic data, Fontaine[3] considers it probable that the electrophoretic fractions in human milk whey closely correspond to different proteins found in bovine whey (serum albumin, β-lactoglobulin, α-lactalbumin and immune globulins). As part of an investigation of the protein composition of human milk whey and its relation to bovine whey, I have studied the separation of a crude 'albumin'-fraction from human milk by means of chromatography on calcium phosphate.

Pooled, frozen human milk or fresh milk was used. After defatting the milk by centrifugation, the lactalbumin fraction was obtained by salting out with ammonium sulphate in the following way. A crude fraction consisting of casein and lactoglobulins was removed at 50 per cent saturation. The lactalbumin fraction was then precipitated by saturating the remaining solution with ammonium sulphate. This crude albumin consisted of three main components judging by paper electrophoresis (Fig. 1).

The calcium phosphate gel was prepared according to Tiselius[4]. 250-mgm. samples of lyophilized protein were dissolved in 10 ml. 0·03 M sodium phosphate buffer pH 6·9, containing 0·1 M sodium chloride. This solution was applied to calcium phosphate columns, 2·8 cm. × 8 cm., previously washed with the same buffer solution. Elution was performed with a slight external pressure giving a flow-rate of approximately 20 ml./hr. The effluent was collected in 5-ml. fractions and the protein concentration of each

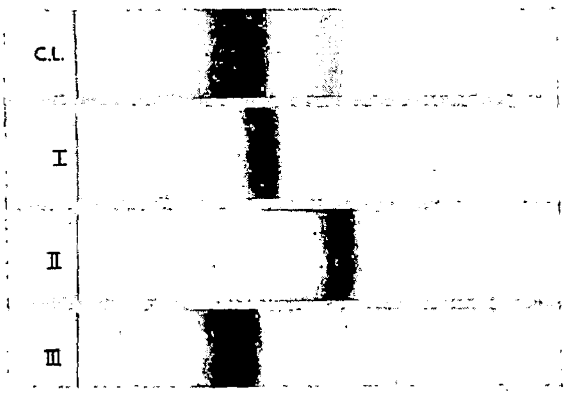

Fig. 1. Paper electrophoretic patterns of crude, human lactalbumin (*C.L.*) and different fractions obtained by chromatography on calcium phosphate

fraction arbitrarily determined at 280 mμ in a Beckman *DU* spectrophotometer. A typical chromatogram is shown in Fig. 2. Elution with step-wise increased concentrations of phosphate buffer gave three peaks at 0·03 M, 0·12 M and 0·5 M, respectively. With these concentrations no considerable tailing occurred. The different fractions were thoroughly dialysed against ice-cold distilled water and lyophilized. The yields of the different fractions estimated by Kjeldahl determinations were I, 45 per cent, II, 10 per cent, III, 30 per cent, the total yield thus amounting to 85 per cent. The reproducibility of two chromatographic runs on the same albumin preparation was found satisfactory. By paper electrophoretic investigations of the fractions (Fig. 1), fraction I was shown to be essentially homogeneous in veronal buffer at pH 8·6. However, electrophoresis by the moving-boundary method revealed a small impurity with lower mobility (Fig. 3). The protein appeared homogeneous in the ultracentrifuge with a sedimentation constant of 1·73 S., the value of which is very similar to the sedimentation constant of 1·75 S. for α-lactalbumin isolated from bovine milk whey[5]. Fraction II consisted electrophoretically of at least 80 per cent of a protein with the same mobility as human serum albumin. It was also immunologically identical with serum albumin when tested by Ouchterlony's technique[6]. In fraction III mainly a salmon-coloured component was found containing small amounts of iron, which could not be removed by passing the protein through a column with a cation exchange resin ('Dowex 50, X–12') at pH 6·9. Examination of the light absorption of the component in a wavelength range of 350–1,000 mμ revealed only a flat maximum at 460–470 mμ. No Soret band could be obtained.

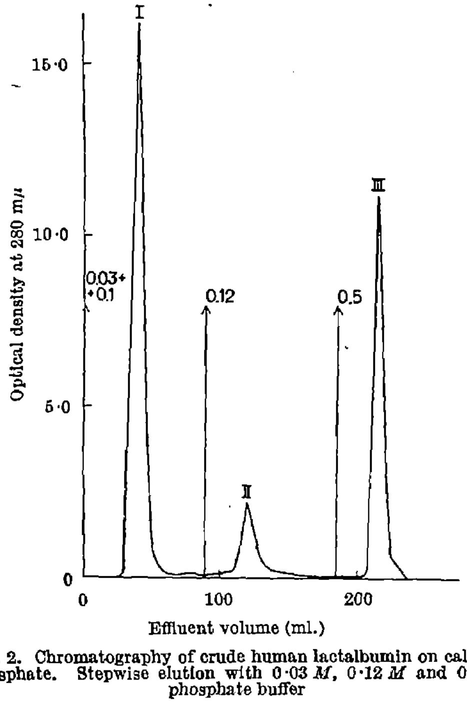

Fig. 2. Chromatography of crude human lactalbumin on calcium phosphate. Stepwise elution with 0·03 M, 0·12 M and 0·5 M phosphate buffer

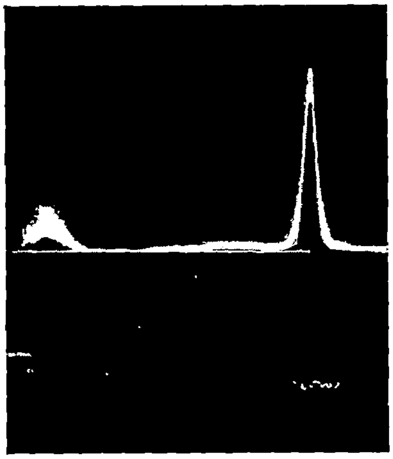

Fig. 3. Boundary electrophoresis of fraction I. Protein concentration 1 per cent. Veronal buffer: pH = 8·6, μ = 0·1. Ascending limb after 7,200 sec.

A more detailed communication concerning the isolation, composition and properties of the fractions described will be published later.

Effect of Neutral Salts on the Structure of Collagen and Gelatin

In a current project in this laboratory, the optical rotatory properties of aqueous solutions of gelatin and soluble collagen from three different species of vertebrates have been examined in the absence and presence of lithium bromide. Results (Table 1) are in general agreement with the earlier work of Carpenter and Lovelace on bovine gelatin[1]. It will be observed that, although striking changes occur in the specific rotations of collagen and gelatin in the presence and absence of salt, the value of λ_c (obtained from the slopes of linear Drude plots of $\lambda^2[\alpha]$ vs. $[\alpha]$)

Table 1. EFFECT OF SALTS ON OPTICAL ROTATORY PROPERTIES OF COLLAGEN AND GELATIN

Material	Solvent	$[\alpha]_D^{25}$*	λ_c (mμ)	$[\alpha]_D$† configuration (calc.)
Rat tail collagen	Water	−289°	217	−200°
Rat tail gelatin	Water	−118°	217	−30°
Rat tail gelatin‡	12 *M* LiBr	−35°	207	+53°
Ichthyocol collagen	Citrate (μ 0·05, *p*H 3·7)	−330°	204	−240°
Ichthyocol gelatin (Ref. 12).	Citrate (μ 0·05, *p*H 3·7)	−110° (41° C.)	204	−20°
Ichthyocol gelatin	2 *M* KSCN	−86°	204	+4°
Ichthyocol gelatin‡	12 *M* LiBr	−56°	202	+34°
Bovine collagen	0·2 *M* KCl	−350°	220	−258°

† For amino-acid compositions of rat-tail, ichthyocol and bovine collagens, see ref. 11.

‡ Prepared by adding lithium bromide solution to the solid collagen.

changes only slightly and, if anything, may decrease somewhat.

The gelatin molecule in solution exhibits hydrodynamic properties approaching those expected for a random chain[2]. Consequently, a lowering of the water activity through addition of lithium bromide should favour a hydrogen-bonded configuration, as is observed in the case of oxidized ribonuclease, clupein, silk fibroin and serum albumin[3]. On the other hand, the high proline and hydroxyproline content of gelatin is not compatible with the formation of an α-helix if we assume that the proline residues do not exist as blocks in the polypeptide chain[4]. Moreover, a number of observations have demonstrated that the transition from a partially folded or random polypeptide chain structure to an extensively hydrogen-bonded configuration, although leading to a decrease in the absolute value of the specific rotation, is invariably reflected in an increase[5] in the value of the Drude dispersion parameter, λ_c, of between 30 and 100 mμ. Such a transition for a polypeptide chain of the molecular weight of bovine gelatin ($2–4 \times 10^5$ (ref. 2)) should also lead to a significant increase in the intrinsic viscosity of the solution. However, viscosity measurements on solutions of a commercial bovine gelatin in 0·2 *M* potassium chloride and in 8·5 *M* lithium bromide at a temperature of 35° C. yield, within the experimental error, the same intrinsic viscosity, namely, 0·39 (gm./100 ml.)$^{-1}$. The optical rotatory properties of gelatin in the presence of high concentrations of neutral salts cannot, therefore, represent the development of any extensive hydrogen-bonded configuration.

Recently[6], we have found significant alterations in the optical rotatory characteristics of aqueous solutions of poly-L-proline II[7] in the presence of lithium bromide and certain other salts. (Poly-L-proline exists in two forms, one exhibiting a specific rotation $[\alpha]_D^{25} = +40°$ in water (polyproline I) and the other exhibiting a specific rotation, $[\alpha]_D^{25} = -540°$ (polyproline II).) Thus $[\alpha]_D^{25}$ decreases from a value of $-540°$ (in water) to about $-250°$ (in 12 *M* lithium bromide), whereas, from linear Drude plots of the rotatory dispersion, λ_c is lowered from 202 mμ to about 185 mμ. These changes have been interpreted as resulting from a series of *trans–cis* isomerizations at the proline–proline peptide bonds of the polymer. Whatever the true nature of these changes, it would seem possible for similar phenomena to occur in solutions of soluble collagen and gelatin in lithium bromide, resulting in the optical rotatory properties described above. It should be noted that the repeating sequence glycine–proline–hydroxyproline, which chemical evidence suggests is common in collagen, would provide the required proline–proline peptide bond.

The specific rotation of a long polypeptide chain which is locked into an asymmetric configuration may be expressed as:

$$[\alpha]_D = \frac{100 \sum_i [R_i]}{n R_m} + [\alpha]_D, \text{configuration}$$

where $[R_i]$ is the intrinsic residue rotation of the *i*th amino-acid residue, R_m the mean residue rotation, *n* the number of residues in the chain, and $[\alpha]_D$, configuration, the structural contribution of the chain. $[R_i]$ of glycine may be taken as zero, that of proline and hydroxyproline[6] as $-250°$, and that of all other amino-acids[6] as about $-110°$. From the known compositions of the three gelatins and their specific rotations we have estimated the structural contribution, $[\alpha]_D$, configuration, in water and in concentrated lithium bromide (Table 1).

Inspection of Table 1 reveals a residual amount of left-handed (−) asymmetry (in the absolute sense, in conformity with the screw sense of polyproline II [9]) remaining in each of the gelatin molecules in water and in dilute salt solutions. Moreover, all the gelatin structures have a significant amount of right-handed (+) configuration in aqueous lithium bromide which, by analogy with the studies on polyproline II, could result from *trans–cis* isomerizations at the proline–proline peptide bonds. The three collagens in water exhibit very strong left-handed structural contributions, the values for $[\alpha]_D$, configuration approaching that found[5] for the proline II helix in water ($-300°$). The possibility that gelatin retains some polyproline II-like structure in water may be of importance in the association of gelatin molecules at low temperature to give the collagen fold[10].

In conclusion, I would point to the similarity between the effects of heat and neutral salts in contracting the collagen fibril and suggest that the shrinkage behaviour of collagen at elevated temperatures in the absence of salt, and at low temperatures in the presence of salt, could be strongly dependent on *trans–cis* isomerizations at the proline–proline peptide bonds.

Structure of an Acidic Polysaccharide elaborated by *Aerobacter aerogenes*

ORGANISMS of the *Aerobacter–Klebsiella* group have been divided[1] into many serologically distinct types each of which produces its own type-specific polysaccharide. Only a few of the structures of these polysaccharides have been elucidated[2-4] since in general they are of a highly complex nature. Recently we isolated an acidic polysaccharide (4·45 gm.) from the culture medium (38·4 l.) of *Aerobacter aerogenes* N.C.T.C. 8172 (*Klebsiella* type 64). The bacteria were grown both in batches and in continuous culture in an apparatus of the type described by Elsworth, Meakin, Pirt and Capell[5]. A peptone–glucose medium was used, the culture was aerated, the *p*H 5·0 and the temperature, 37°. The acidic polysaccharide was freed from neutral polysaccharide by precipitation with 'Cetavlon'[6] and from nucleic acid by the preferential solubility of its cetyl trimethyl ammonium salt in 0·25 *M* sodium chloride. Isolated as its sodium salt, the acidic polysaccharide had C, 45·31 ; H, 6·19 ; N, 0·81 ; P, 0·11 per cent and its ultra-violet absorption at 260 mμ corresponded to about 1·8 per cent nucleic acid impurity. The polysaccharide contained 28·7 per cent uronic acid (by decarboxylation[7]) and the infra-red spectra of the polysaccharide as the free acid and as the sodium salt confirmed the presence of carboxylic acid groups[8]. The polysaccharide showed $[\alpha]_D^{17} + 29{\cdot}4°$ (conc. 0·272 in *M* sodium chloride).

Acidic hydrolysis of the polysaccharide (3·7 gm.) with 2 *N* sulphuric acid (75 c.c.) at 100° for 3 hr. and separation of the neutralized hydrolysate on 'Deacidite *FF*' (carbonate form) gave neutral sugars (2·3 gm.) and acidic sugars (1·03 gm.). Separation of a portion (2·0 gm.) of the neutral sugars on a cellulose column irrigated with butanol, ethanol, water, ammonia (40 : 10 : 49 : 1) gave one fraction (0·295 gm.) containing rhamnose and another (1·5 gm.) containing a glucose–mannose mixture. The rhamnose was obtained as crystalline α-L-rhamnose, m.p. and mixed m.p. 93–94°, $[\alpha]_D^{22} + 8{\cdot}2°$ equil. (conc. 4·13 in water). The glucose–mannose mixture was separated by treatment[9] with *p*-nitroaniline in methanol containing hydrochloric acid to give N-*p*-nitrophenyl-β-D-glucopyranosylamine dihydrate m.p. and mixed m.p. 184°, $[\alpha]_D^{22} - 196°$ (4 min.) → − 203° (equil.) (conc. 1·02 in dry pyridine), and N-*p*-nitrophenyl-β-D-mannopyranosylamine dihydrate m.p. and mixed m.p. 219°, $[\alpha]_D^{22} - 400°$ (4 min.) → − 333° equil. (conc. 0·12 in dry pyridine). Separation of the acidic sugars (1·0 gm.) on a cellulose column irrigated with *n*-butanol–acetic acid–water (4 : 1 : 5) gave fractions containing hexuronic acid (0·02 gm.), aldobiuronic acid(s) (0·41 gm.) and mixtures of these (0·45 gm.). The hexuronic acid and its lactone had mobilities on paper chromatograms identical with those of glucuronic acid and glucuronolactone. Reduction of its methyl ester methyl glycoside with lithium aluminium hydride and acidic hydrolysis of the product gave glucose with traces of mannose. This evidence indicated the presence of glucuronic acid together with a trace of mannuronic acid in the acidic polysaccharide.

Paper chromatographic analysis of an acidic hydrolysate of the aldobiuronic acid fraction showed the presence of unhydrolysed aldobiuronic acid, mannose, glucuronic acid and small amounts of glucose. Similar analysis of a hydrolysate of the reduced aldobiuronic acid fraction showed the presence of approximately equal amounts of glucose and mannose. No rhamnose was detected either in the aldobiuronic acid hydrolysate or that of its reduction product. This evidence indicates that the major component of the aldobiuronic acid fraction was a glucuronosyl–mannose.

The acidic polysaccharide consumed 0·303, 0·331, 0·337 and 0·423 moles of periodate per 162 gm. of polysaccharide after oxidation for 48, 72, 96 and 110 hr. respectively. The corresponding values for formic acid produced were 0·06, 0·091, 0·1 and 0·11. Paper chromatographic analysis of a hydrolysate of the periodate oxidized polysaccharide showed the presence of glucose, mannose and glucuronic acid, but no rhamnose. These results indicate (*a*) that rhamnose is present either as end groups or linked through the 2- or 4-position, (*b*) that the maximum number of residues present as end groups or linked 1 : 6 is about 11 per cent, (*c*) that most of the glucuronic acid residues are not end groups and (*d*) that large numbers of glucose, mannose and glucuronic acid residues are linked either 1 : 3 or are involved in branching.

Colorimetric Detection of Human Cæruloplasmin Oxidase Activity after Electrophoresis in Agar Plates or after Immuno-electrophoresis

THE use of colour reactions combined with electrophoretic analytical methods in agar plates has allowed double (electrophoretic mobility and chemical nature) or triple (electrophoretic mobility, immunochemical specificity and chemical nature) characterization of proteins, lipids, glycoproteins and phospholipids in a variety of biological fluids[1].

Cæruloplasmin, the blue protein of human serum, was isolated in 1948 by Holmberg and Laurell[2] and characterized as an α_2-globulin containing copper. They also showed that the substance exhibited oxidase activity with a variety of substrates.

In previous work[3], we have studied this protein by electrophoretic and immuno-electrophoretic analysis followed by the colorimetric detection *in situ* of copper-bound cæruloplasmin. In order further to identify cæruloplasmin by another of its inherent properties, we have also developed a method for the detection of its oxidase activity.

The oxidizable substrates that we employed have previously been used in manometric[2] and spectrophotometric[4] methods for the estimation of the oxidase activity of cæruloplasmin. The method to be described is based on the fact that the final oxidation product of *p*-phenylenediamine is a quinoid compound insoluble in water called Bandrowski's base[5]. The formation of this deep brown base makes possible *in situ* measurement of the enzymatic activity of cæruloplasmin on compounds which have first been submitted to electrophoretic or immuno-electrophoretic analysis in agar gel. The apparatus employed and the method of agar electrophoresis have been described by Grabar and Williams[6].

Samples of human serum (0·02 ml. per analysis) or a solution of cæruloplasmin in 0·06 *M* sodium chloride (50 μgm. per analysis) are subjected for 4–5 hr. to a potential difference of 4–5 V./cm., in 1–1·2 per cent agar gel (3–4 mm. thick) containing a veronal buffer (*p*H 8·2, Γ/2 0·03).

We have employed the immuno-electrophoretic method of Grabar and Williams using the serum of horses immunized against whole human serum. When the lines of specific precipitation have formed, the plates are washed for three days in a solution of 0·15 *M* sodium chloride, which is changed once or twice a day.

After electrophoresis or after immuno-electrophoresis, the procedure is continued in the following manner. The plates are immersed in a 5×10^{-3} *M* solution of *p*-phenylenediamine in acetate buffer (*p*H 5·7, Γ/2 0·1) prepared immediately before use. In this solution they are incubated at 37° C. for 2 hr. At the end of the incubation period the position of the portions with oxidase activity is indicated by brownish spots or lines.

The plates are then washed twice for successive periods of two hours each in a solution of sodium acetate–acetic acid buffer (*p*H 4·7, Γ/2 0·1). This stops enzymatic activity and rids the agar plates of excess *p*-phenylenediamine. A typical result of such a run with normal human serum is shown in Fig. 1. The oxidase activity is seen as a zone corresponding to that of α_2-globulin. Only one of the lines of precipitation corresponding to the 18–20 antigenic constituents of human serum possesses oxidase activity with regard to *p*-phenylenediamine. The groups responsible for enzymatic activity are not blocked by the antigen–antibody combination. When sodium azide (10^{-3} *M*) is added to the solution of oxidizable substrate all enzymatic activity of the cæruloplasmin is destroyed.

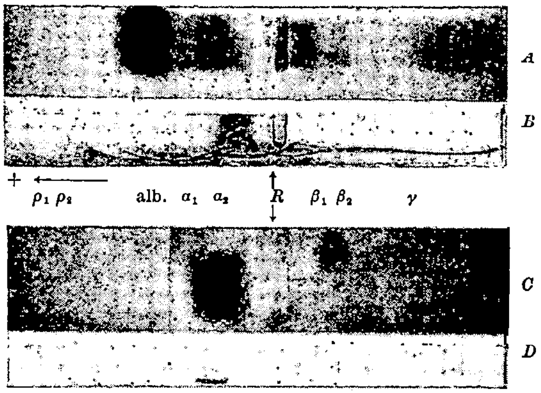

Fig. 1. *A*, Agar electrophoresis, a typical serum pattern stained with amidoschwarz; *B*, immuno-electrophoresis of human serum, lines of specific precipitation stained with azocarmine; *C*, oxidase activity in serum after agar electrophoresis; *D*, oxidase activity in serum after immuno-electrophoresis; *R*, starting place

Methods for the estimation of oxidase activity of cæruloplasmin in whole serum, either by oxygen consumption in the Warburg apparatus or by spectrophotometric determination, are open to the criticism that other redox systems in serum may act as competitive inhibitors on the substrate, *p*-phenylenediamine. Preliminary dialysis of the serum might prevent such interference in the case of small molecules (ascorbic acid, etc.), but it would be ineffective in the case of certain reducing groups on the surface of protein molecules.

With our technique the risk of encountering such difficulties is considerably lessened because of the preliminary electrophoretic separation of the protein constituents of the serum, and is practically negligible after immuno-electrophoretical analysis. We are now studying the exact conditions necessary for the quantitative estimation *in situ* of this enzymatic activity; preliminary results indicate that it will be possible to obtain quantitative measurements with the method[7].

A similar procedure to that reported here has been applied to the detection of catalase and peroxidase activities in hæmoglobin after electrophoretic separation in agar gels[7].

Microwave Spectra of Diazomethane and its Deutero Derivatives

WE have measured rotation spectra, in the frequency-range 19,000–90,000 Mc./s., for three isotopic forms of diazomethane, and obtained the constants shown in Table 1, in Mc./s. A preliminary value of $1{\cdot}4_5 D$ is obtained for the dipole moment of diazomethane from Stark effect measurements on the $0_{00} \rightarrow 1_{01}$ transition. Nuclear quadrupole hyperfine structure is resolvable; its analysis is at present incomplete.

Table 1

Molecule	$(B_0 + C_0)$	$(B_0 - C_0)$	D_{JK}	D_J
CH_2N_2	22,150·7±0·2	460·2±0·2	0·39±0·01	<0·01
$CHDN_2$	20,640·7±0·2	578·3±0·2	0·27±0·01	<0·01
CD_2N_2	19,389·0±0·2	696·2±0·2	~0·2	—

The constants for CH_2N_2 correspond to a value of $(B_0 + C_0)/2$ equal to $0{\cdot}369433 \pm 0{\cdot}000004$ cm.$^{-1}$, compared with 0·368 cm.$^{-1}$ obtained from infrared spectra by Mills and Thompson[1], and with 0·371 cm.$^{-1}$ derived from similar data by Fletcher and Garrett[2]. Our results are consistent with the planar structure with C_{2v} symmetry indicated by the infra-red spectra. The moment of inertia, I_A, found for CH_2N_2 from the relationship $I_A = I_B - I_C$ is $3{\cdot}15 \times 10^{-40}$ gm. cm.^{2}, which is slightly greater than the value reported from infra-red measurements[2]. Independent estimates of I_A from the present microwave R-branch transitions are in agreement, but are necessarily approximate, and we expect to determine accurate values of I_A from Q-branch spectra. In view of the inertial quantum defect found for ketene, a rather similar molecule, from its microwave spectrum[3], the present agreement with the infra-red value of I_A is satisfactory.

If any quantum defect is ignored, and the effects of zero-point energies on internuclear distances are neglected, the following structure-parameters are consistent with the microwave data : $d_{\rm CH} = 1{\cdot}08$ A., $\angle$HCH = 127°, $d_{\rm CN} = 1{\cdot}32$ A., $d_{\rm NN} = 1{\cdot}12$ A. and $d_{\rm CN} + d_{\rm NN} = 2{\cdot}442 \pm 0{\cdot}005$ A. Because the central nitrogen atom is very close to the centre of gravity of the molecule, all the parameters, except $d_{\rm CN} + d_{\rm NN}$, can be varied considerably in proper phase with each other without excessive disagreement with the data. The above has been selected from the possible structures as reasonably consistent with all the evidence. There is general agreement with the electron diffraction results[4], but $d_{\rm CN} + d_{\rm NN}$ is considerably shorter than the upper limit allowed by the diffraction data.

To date we have detected no spectra attributable to a tautomeric form of diazomethane, the presence of which was suggested from infra-red evidence by Mills and Thompson[1]. A further search for such absorptions will be made, but there are indications[5] that the stability of the tautomer may be no greater than that of normal diazomethane, which decomposes with a half-life of the order of a minute in wave-guide cells of copper or coin-silver cooled to − 70° C. for most of their length.

Other aspects of the spectra are under investigation, and detailed results will be communicated later. We are grateful to Mr. J. S. Heeks for assistance with these measurements.

Correlations between Localization Energies and Polarographic Half-Wave Potentials of Aromatic Hydrocarbons

Basu and Bhattacharya[1] recently claimed to have established a linear correlation between *para*-localization energies and polarographic half-wave potentials for some polynuclear hydrocarbons. Objections to their work have been raised by Pullman[2] and Fernandez-Alonso and Domingo[3], who criticize the values of the localization energies selected by Basu and Bhattacharya. All these authors use the polarographic data of Wawzonek and Laitinen[4], but all of them appear to have misunderstood the latter workers' statement that polarographic reduction consists of a two-electron addition process. It is true that the overall reaction consists of the addition of two electrons. But it is clear from the work of Wawzonek and Laitinen themselves, as well as from that of later authors[5-7], that the addition takes place by two one-electron steps. The least negative half-wave potential might therefore be expected to characterize the energy required to add *one* electron to the aromatic system, but could scarcely be related to the *para*-localization energy, which is a measure of the ease of addition to *two* positions in a hydrocarbon simultaneously[8].

A correlation between half-wave potentials and the localization energy for a single position is to be expected, since a straight line relation has already been reported between the latter and the logarithm of the methyl affinity[9,10], and another between log (methyl affinity) and half-wave potential[11]. This expectation is realized fairly satisfactorily in Fig. 1, where half-wave potentials measured in 'Cellosolve' solution by Bergman[12] are plotted against localization energies calculated by Coulson[9] (see also ref. 13), and by Dewar[14]. But it may be questioned whether this last correlation has theoretical significance, for the following reason. Coulson[9] and Szwarc[10] in relating methyl affinities to localization energies made the usual assumption that in the transition state the methyl radical is bound to a particular carbon atom which has sp^3 hybridization. On the other hand, Matsen[11], in correlating methyl affinities with half-wave potentials, suggested that the odd electron of the radical enters the lowest unoccupied orbital without binding the methyl to any particular carbon atom ; electrons added by polarographic reduction are also believed (for example, ref. 15) to enter the π-electron system in the same way and thus be delocalized. Hence the bases of the two earlier correlations seem to be incompatible.

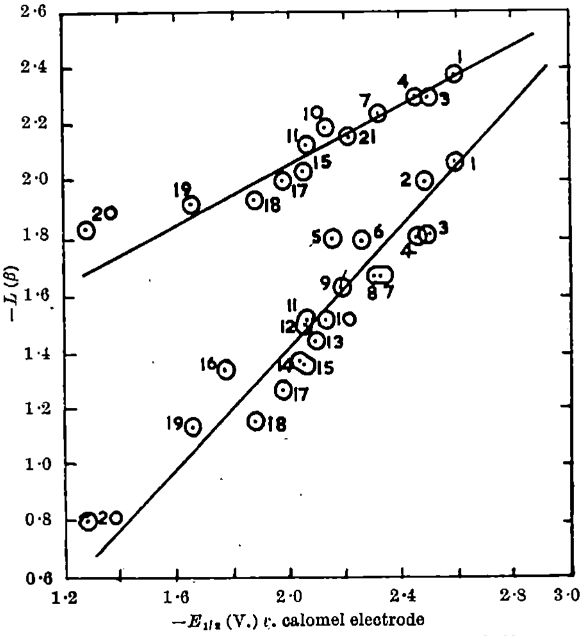

Fig. 1. Relations between localization energies and half-wave potentials. (*Upper curve*, localization energies of Coulson ; *lower curve*, those of Dewar.) *Key :* 1, diphenyl ; 2, triphenylene ; 3, naphthalene ; 4, phenanthrene ; 5, coronene ; 6, 3 : 4-benzophenanthrene ; 7, chrysene ; 8, picene ; 9, 1 : 2-benzopyrene ; 10, pyrene ; 11, 1 : 2-5 : 6-dibenzanthracene ; 12, 1 : 2-3 : 4-dibenzanthracene ; 13, 1 : 2-7 : 8-dibenzanthracene ; 14, pentaphene ; 15, 1 : 2-benzanthracene ; 16, perylene ; 17, anthracene ; 18, 3 : 4-benzopyrene ; 19, naphthacene ; 20, pentacene ; 21, *trans*-stilbene

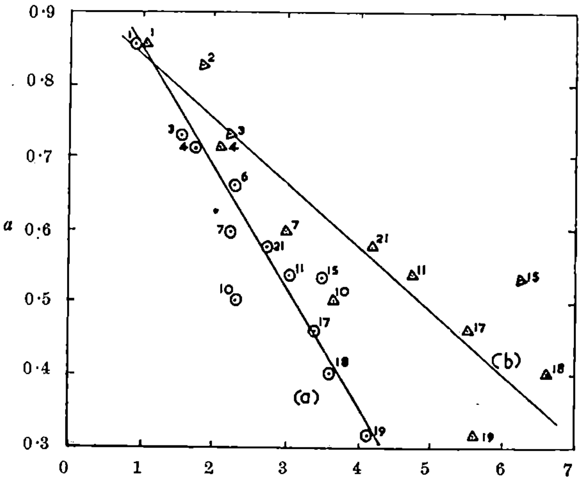

Fig. 2. Relations between partial rate factors of free radical additions and the root a of molecular orbital secular equation. (a), Addition of methyl; (b) trichloromethyl. (For key to points, see caption to Fig. 1)

This incompatibility may be less serious than appears at first sight: it has been pointed out[8] that the state visualized in the concept of localization energy is farther along the reaction path than the transition state (see also ref. 16), and therefore Matsen's suggestion may correspond to a different state, closer to the transition state itself. If this were true then the root, a, of the molecular orbital secular equation corresponding to the lowest unoccupied π-electronic level of aromatic hydrocarbons should predict correctly the relative reactivity of hydrocarbons to free radicals (assuming the resonance and overlap integrals to be constant). In Fig. 2 the logarithms of the partial rate-constants (relative to benzene) of the reactions of aromatic hydrocarbons with methyl[17] and with trichloromethyl radicals[13] are plotted against a (the rate-factors have all been divided by the number of equivalent positions of attack; the values of a were taken from Hoijtink[15] and were calculated on the assumption that $S = 0{\cdot}25$). The correlation is satisfactory for the methyl additions—only two points are seriously off the line—but is less so for the reactions of trichloromethyl; however, the experimental data for the latter are less precise[13].

Inasmuch as Hoijtink[15] and others have found a good straight-line relation between a and half-wave potentials of aromatic hydrocarbons, the correlation with rates of radical addition is not an independent one (since its existence could have been predicted from the other relations mentioned above). Indeed, a number of similar correlations have been described in the literature recently, such as Coulson's of log (methyl affinity) with free valency[9] and Szwarc's of the same parameters with singlet–triplet excitation energies[10]. Others are implicit in those already reported—for example, half-wave potentials with singlet–triplet excitation energies. Not all the correlations referred to in this communication can be of fundamental significance; distinguishing the fundamental from the coincidental should be a fruitful study for those concerned with the theory of reaction mechanism.

As already stated, the polarographic data of Bergman[12] were used in plotting Fig. 1; the half-wave potentials determined by Hoijtink *et al.*[6] using a 96 per cent dioxan–water mixture as solvent are on the whole closely similar to those of Bergman, but give a slightly less satisfactory plot against localization energy.

Niobium in Sea-water

The presence of organically bound niobium has been demonstrated in ascidians[1], and unpublished evidence suggests that this niobium is absorbed in some way from sea-water. It is thus of importance to know if niobium can be detected in sea-water and to obtain some indication of its concentration. Consideration of the known amounts of niobium present in an adult *Molgula manhattensis*, its rate of development, length of life and rate of filtration of water leads one to suppose that if the water current is the sole source of niobium then, in regions where these species and other species of ascidians which utilize niobium flourish, it cannot be present in the sea in less concentration than 0·05 μgm./l. The chromatographic method of niobium analysis developed by Hunt, North and Wells[2] is capable of revealing the presence of 10^{-7} gm. of niobium. At a concentration of 0·05 μgm./l., this amount could be expected in 2 l. of sea-water.

For analysis, therefore, 20-l. samples were utilized. A known amount of niobium-95 was added to each sample, and the radioactivity of an aliquot assayed. To the remainder was added 175 μgm. of ferric iron. The pH was adjusted to 9·9–10·0 by the slow addition of ammonia with constant stirring. After settling, as much as possible of the supernatant was decanted off and the precipitate recovered by filtration. The precipitate was dissolved in a minimum quantity of hydrofluoric acid, transferred to paper, dried thoroughly and chromatographed using ethyl methyl ketone containing 15 per cent v/v of 40 per cent hydrofluoric acid. On the completion of the run the paper was dried and, after exposure to ammonia vapour, sprayed with a 2 per cent solution of tannic acid. Niobium was, under these conditions, detected as a narrow orange-yellow band in the solvent front. Estimation of the amount present was achieved by comparison with standards of varying amounts of niobium, each co-precipitated with 175 μgm. of ferric iron and chromatographed under identical conditions. After estimation of the amount present in each sample, the radioactivity of the paper strip was assayed to determine the proportion of niobium-95, and hence also of niobium-93, which had been recovered in the analysis. A correction based on this figure could then be applied. The recovery was always better than 50 and usually near 80 per cent. Additional tests were carried out using samples of seawater to which known amounts of niobium-93 had been added.

In water taken in summer from the sea surface at International Hydrographic Station *E*1 (about 40 km. south-west of Plymouth) no niobium was detected by this method if the water was first filtered through Whatman filter paper 542 or through a fine porcelain filter candle. With unfiltered water, however, niobium appeared to be present at a concentration of 0·01–0·02 μgm./l. Bottom water, which may differ widely, has not yet been analysed. In filtered water taken from Plymouth Sound niobium was detected at a concentration of 0·005 μgm./l., while in unfiltered water the concentration reached a level of 0·05–0·1 μgm./l., though in conditions of settled weather with little land water draining into Plymouth Sound the figure was sometimes as low as 0·01 μgm./l.

Free-Radicals produced in Cigarette Smoke

IN attempts to determine a unifying principle of action for the many and varied carcinogenic agents, many workers have assigned an intermediary role to free radicals. The action of ionizing radiation and radiomimetic agents in this respect has been discussed by Brues and Barron[1]. It is stated that many, if not all, carcinogens are compounds capable of forming free radicals which may be stabilized as ions[2]. Oppenheimer *et al.*[3] discussed their possible role in the production of tumours in rodents by implanted films of various high polymers, and suggested, as a requirement for tumour production, the presence of foreign free radicals in a specific area for an extended period.

Primary consideration is normally given to aromatic polycyclic hydrocarbons as active agents in tobacco carcinogenesis. However, in view of the above, it seemed of interest to determine the concentration of free radicals in cigarette smoke. The following series of experiments, which utilized a high-sensitivity electron resonance spectrometer[4], have therefore been carried out. In order to prevent recombination of radicals as much as possible, the smoke was condensed at liquid-oxygen temperatures, and all measurements were made at this temperature.

British-type cigarettes were smoked in a manner simulating the normal human habit. The cigarettes were fixed in a small manifold which was connected to a filter pump so that intermittent drawing was possible. A sealed-off length of $\frac{1}{4}$-in. diameter tubing led down from the manifold chamber. This tube was immersed in liquid oxygen during smoking. A portion of the smoke was found to condense out in the tube as a pale yellow solid. When about $\frac{1}{2}$ gm. of condensate had been collected, the apparatus was quickly transferred to the electron resonance spectrometer and the tube was inserted into the centre of an H_{014} cavity, surrounded by liquid oxygen. The concentration of radicals in the deep-frozen material was then determined using 100 kc./s. modulation and phase-sensitive detection, so that the free-radical absorption was traced out as a derivative on the pen-recorder. The smoking apparatus was then removed from the spectrometer and the condensate in the tube was warmed to 60° C. for about five minutes so that any active radicals could recombine. The tube and contents were then deep-frozen, re-inserted in the spectrometer and the concentration of radicals again measured. In this way it was possible to distinguish between short-lived, active radicals and those that were stabilized sterically or by resonance[5].

The concentration of radicals obtained in the frozen smoke condensate before warming was of the order of 10^{15} free electrons per gm. It should be noted that this condensate contains large amounts of solid carbon dioxide and ice. On warming, the condensate separated into an aqueous and an organic or tarry phase. No radical concentration at all could be detected in the aqueous phase, and that in the organic phase was reduced by a factor of six approximately. The radicals that could still be detected in the latter were found to be highly stabilized, and no diminution of their concentration was found after several days.

It would therefore appear from these experiments that the tar constituents of cigarette smoke contain about 6×10^{15} free electrons/gm. Some of these radicals, being relatively short-lived, disappear when the condensate is warmed to 60° C. for some minutes. The remainder, however, appear to be very stable and long-lived.

Another set of experiments was carried out with the stable radicals, and their concentration after chemical fractionation was investigated. For this, cigarette smoke was trapped in a series of wash-bottles containing benzene at room temperature. Aliquots of this solution were washed a number of times with (*a*) water, (*b*) 2 *N* sodium hydroxide, (*c*) 2 *N* sulphuric acid, (*d*) 2 *N* sodium hydroxide and then 2 *N* sulphuric acid; (*b*), (*c*) and (*d*) were finally washed with water. The solvent was removed from the various extracted solutions and the free-radical concentrations of the resulting tars compared with a sample of unextracted whole tar by the method outlined above.

A decrease in the initial concentration of free radicals in whole tar was found to follow the various extractions. Washing with water reduced the initial concentration by 20 per cent, with alkali by 50 per cent, with acid by 57 per cent, while washing with alkali followed by acid reduced the concentration by 72 per cent. It would appear from this that a number of different species of free radicals exist in the stable group.

The combined evidence from these experiments suggests that there is sufficient concentration of free radicals in cigarette smoke (when compared with the expected concentrations in the polymer experiments[3]) to act as a carcinogenic agent if such a mechanism is possible. It is interesting to note in this connexion that the concentration of stable free radicals in atmospheric soot is about one hundred times larger than in cigarette smoke. But, as with the polycyclic hydrocarbons[6], adsorption on comparatively larger particles, and further stabilization as a result, are likely to render them inaccessible to the cells.

Most bioassays in tobacco carcinogenesis studies have been carried out using either condensates, which are afterwards taken up in solvents at room temperatures, or tars derived from smoke trapped in organic solvents. It is now clear that such materials are deficient in unstable free radicals initially present in smoke. The free-radical content of cigarette smoke as a parameter in the etiology of lung cancer would therefore seem to be a reasonable possibility.

Second Virial Coefficient of Methyl Chloride Vapour

Theoretical considerations, for example, those of Hirschfelder[1], indicate that the virial coefficients higher than the second cannot be large enough to produce, in the isotherms of vapours at reduced temperatures near 0·70, sufficient curvature to be detectable with the experimental techniques available at present. Nevertheless, there are several statements of curved isotherms in the literature. As pointed out previously[2,3], the greatest care is required if errors due to adsorption are to be avoided.

Hamann and Pearse[4] report measurements by a differential compressibility method on methyl chloride and methyl bromide and find that, at the low temperatures, there is an apparent non-linearity of PV with P which they attribute to either higher virial terms or to adsorption. In these experiments the vapour was compressed before an advancing mercury surface. By making reasonable estimates from the data of Bottomley and Reeves[3], it is clear that the non-linearity observed is of the order to be expected from neglect of the adsorption on the surfaces of the apparatus.

That adsorption errors are indeed responsible for this non-linearity is confirmed by experiments which we have carried out recently. The isotherms of methyl chloride have been determined at 22° C. in a differential compressibility apparatus similar to that used previously for xenon[5]. A strictly linear isotherm has been obtained over the pressure-range 750–150 mm. of mercury with eleven experimental PV values at both rising and falling pressures which show a mean deviation of ± 4 in 100,000 from the least-mean-square line. Adsorption has been rendered negligible by two factors. The surface/volume ratio is much lower in our experiments, and the bulbs containing the vapour were made of high-quality silica, which is much less adsorptive than other glasses.

In differential compressibility apparatus in which gas volumes are brought to the same pressure by a mercury manometer, there is a potential error. The mercury surfaces on the two sides of the null manometer are exposed to different gases: if one side contains a vapour near saturation the adsorption on the mercury surface may lower the interfacial tension, and hence the capillary depression, so that apparent equality in the two sides of the manometer does not correspond to equal pressures. This correction increases with increasing pressure of vapour, and is in the sense that equal mercury-levels correspond to the pressure of the vapour being greater than that of the non-adsorbed gas. Hamann and Pearse used a manometer tube of 5·7 mm. bore, giving a depression of about 1 mm., so that a mere 10 per cent change in depression amounts to a considerable uncertainty in pressure. Our null manometer is of 35-mm. bore (depression less than 0·001 mm.), and the associated difficulty of a large dead space is eliminated by a direct measurement of volume at each setting.

The final value for the virial coefficient for methyl chloride from our experiments is 416 ± 1 $cm.^3$/mole at 22° C.

Promoting the Stable Eutectic Reaction in Magnesium-treated Iron Castings by Vibration during Solidification

By adding magnesium to cast iron in such a way that a few hundredths of a per cent are retained in solution it is possible to suppress the stable eutectic reaction, and in iron so treated the metastable reaction occurs instead, resulting in castings which contain large amounts of iron carbide. Addition (after the magnesium has been dissolved) of about 0·5 per cent of ferro-silicon (containing 80 per cent silicon) favours occurrence of the stable eutectic reaction during subsequent solidification, and spheroidal-graphite particles are so produced[1]. The ferro-silicon alloy inoculates the stable eutectic.

It has now been discovered that the stable eutectic may also be inoculated by vibrating the mould during solidification of the casting. In this way magnesium-treated cast iron, which would normally solidify primarily by the metastable process, is caused to solidify by the stable process, with precipitation of spheroidal graphite.

Castings substantially free from iron carbide have been produced in this way from magnesium-treated metal containing less than 0·2 per cent silicon, cast into graphite moulds. In such a case the combined effects of magnesium, low silicon content, and high rate of solidification normally preclude graphitization during solidification, even if ferro-silicon is added as inoculant. Nevertheless, castings in the form of balls 2½ in. in diameter, almost completely free from carbide and containing spheroidal graphite, have been produced under these conditions by vibrating the mould at a frequency of 100 cycles/sec. and with an amplitude of 0·040 in.

Iron castings of this composition and having such a structure, as cast, have never previously been reported. The mechanism whereby this effect is produced is not yet understood.

Surface Hardening of Non-ferrous Metals by Spark Discharge

An earlier communication[1] from this Laboratory described experiments in which the thermal action of electric sparks was used to simulate the effects of frictional heating on the structure of rubbing steel surfaces. The high local temperatures which characterize rubbing contacts can, in certain circumstances, initiate austenite formation and, since conduction into the bulk metal provides effective quenching of the hot spots, martensite is formed and causes hardening of the surface layer. Similarly the brief but intense heat of an electric spark, struck between an electrode and the steel surface, can harden a small volume of material. If the sparking electrode traverses the surface a hard and wear-resistant skin develops.

There is evidence[1] that during frictional heating nitrogen and carbon can enter the surface from the atmosphere or lubricant and contribute to the hardness of the transformed product. Likewise during spark heating, the nature of the medium which the spark traverses is of importance in determining the constitution and properties of the hardened layer. Thus nitrogen assimilated during air sparking and carbon during sparking in oil can cause intense hardening (~ 900 V.P.N.) even of pure iron. It is, however, well known that, in sparking contacts, material may be transferred from one member to the other. If, therefore, a steel surface is sparked with an electrode of dissimilar metal, this transferred material can be expected to alloy with the steel and may also react with components of the environment to form hard compounds. By appropriate choice of electrode material and sparking medium, the hardness attained might considerably exceed that of quench-hardened steel.

Recent publications[2] reveal that surface hardening by spark discharge has been developed in the U.S.S.R. as a commercial process for improving wear resistance, and many successful applications are claimed. The surface to be treated is traversed with a vibrating electrode which repetitively discharges current from condensers. The sparking potential and capacitance usually fall within the range 50–220 V., 20–350 μF., the electrode having positive polarity to facilitate transfer of material to the cathode, namely, the workpiece surface. Electrodes of sintered tungsten and titanium carbides are commonly employed, and transfer of these carbides plays an important part in conferring wear resistance.

The Russian literature deals exclusively with the spark-hardening of ferrous metals. While, in general, non-ferrous metals cannot be expected to harden intensively by thermal cycling alone, the ability of the spark to transfer, or even generate, hard substances indicates means by which surface-hardening might be effected. Work in this Laboratory has shown that many non-ferrous metals can in fact be surface-hardened if suitable techniques are adopted. Two main principles can be recognized.

(1) Transfer takes place from an electrode of material, such as sintered carbide, which is already hard, the hardness of the alloyed layer produced tending towards that of the electrode material (1,300–1,700 V.P.N. in the case of cobalt-bonded tungsten carbide). Alternatively, the electrode may consist of material which is not initially hard but which hardens in the spark reaction as, for example, an electrode of steel or of a non-ferrous metal of the type to be discussed.

(2) Certain non-ferrous metals, notably those belonging to the fourth and sixth groups of the Periodic Table, will form extremely hard compounds by chemical reaction with elements easily made available in the sparking zone. For example, carbides of great hardness (1,300 V.P.N. to more than 2,000 V.P.N.) can be formed on the surface of titanium, zirconium, molybdenum and tantalum by sparking in a carburizing environment. This environment can be provided by sparking with a carbon electrode, or through the agency of liquid hydrocarbons or powdered graphite in contact with the surface.

The hardened layer produced by sparking is only a few thousandths of an inch in thickness, but, as the curves of Figs. 1 and 2 reveal, this thin skin can confer greatly improved wear resistance. The wear measurements were made by loading a cylinder of the non-ferrous metal against a rotating ring of hardened tool steel, no lubrication being provided. The sparking of nickel with an electrode of sintered tungsten and titanium carbides (Fig. 1) has produced a 600-fold reduction in rate of wear through the transfer of carbide to the nickel surface. Improvements of similar magnitude have been obtained by this technique on copper, brass, titanium and aluminium. The reduced rate of wear of iodide-titanium illustrated in Fig. 2 is the result of a skin of titanium carbide produced by sparking with a titanium electrode in the presence of mineral oil.

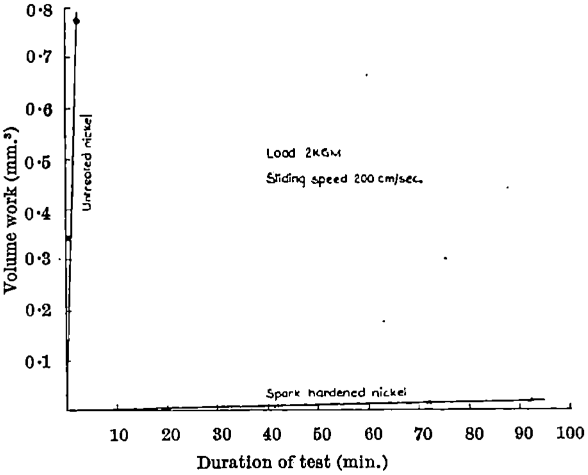

Fig. 1. Change of rate of wear produced by spark-hardening nickel

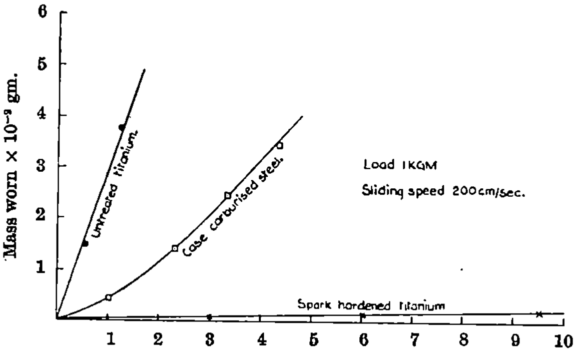

Fig. 2. Change of rate of wear produced by spark-hardening titanium, and comparison with case-carburized steel

For comparison a wear curve for mild steel, case-carburized by conventional means and tested under the same conditions, is also shown in Fig. 2. In these particular rubbing circumstances the spark-hardened titanium is plainly of superior wear-resistance, and it seems likely that spark-treated non-ferrous metals will find applications for wear-resistant parts in engineering practice.

A fuller account of this work will be published in due course.

Strength of Glass Fibres

Previous workers have reported that the tensile strength of nominally identical glass fibres is very inconsistent, with coefficient of variation between 5 and 25 per cent[1,2]. In an attempt to reduce this variability, I have made and tested 'E' glass fibres under carefully controlled conditions. The fibres were drawn from molten glass in a platinum crucible, and were wound around a rotating drum. Only that part of the fibre between the crucible and drum was used for testing. The manipulation technique involved gripping the free length of fibre at its two ends, and mounting it with vacuum wax on a slotted paper mount, which when cut into pieces provided ten test pieces each 1 in. long. Each test piece on its mount was assembled in a special 'chain-o-matic' testing machine with controlled rate of loading, and the mount was severed before application of load. By this means it is possible readily to test large numbers of fibres with surfaces which are mechanically undamaged. To reduce atmospheric attack each batch of ten test pieces was tested within two minutes of manufacture, and in an atmosphere of less than 40 per cent relative humidity.

Using the above technique I have been able to obtain fibres of remarkably consistent strength; on some occasions the coefficient of variation of breaking stress of ten test pieces has been only 1 per cent.

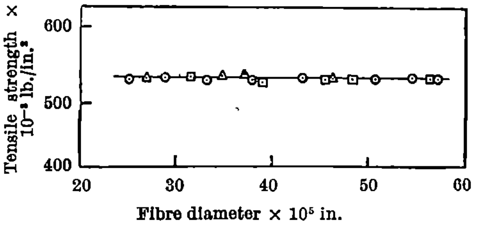

Fig. 1. Temperature of glass in crucible. △, 1,340° C.; ○, 1,300° C.; □, 1,260° C.

Another observation was also made. Over the range for which fibres of uniform diameter can be drawn with my apparatus (2–6 × 10^{-4} in.), the breaking stress is independent of fibre diameter and of the temperature of the glass in the crucible; it is also independent of the rotational speed of the drum. The results are illustrated in Fig. 1. Each point is the mean breaking stress of ten test pieces. Previous workers using different testing techniques have found a very appreciable reduction in breaking stress with increase in diameter for the range shown in Fig. 1.

Spiral Pits on Silicon Carbide

The dislocation theory of crystal growth[1] suggests that the crystal growing at low supersaturation in the presence of a single dislocation is not composed of an infinite number of layers stacked on each other as ideally considered, but is a helicoid with the dislocation line as its axis and the point of emergence of the dislocation at the top. The observation of a growth hill in the form of a 'spiral staircase' on a number of crystals reported in recent years[2] has amply substantiated the theoretical predictions. Silicon carbide crystals have afforded evidence[3] of a large variety of spiral growths, for example, monomolecular as well as microscopic, and interaction of spiral growth due to two or more dislocations of same as well as of opposite sign. In some cases, hitherto unobserved, silicon carbide crystals exhibit spirally terraced pits. Fig. 1 shows a phase-contrast micrograph of a spirally terraced pit. It is easy to decide with the fringes of equal chromatic order that this feature is a pit. The step height of this terraced pit as determined from high-dispersion Fizeau fringes corresponds to 27 ± 2 A., which is the repeat distance of this crystal identified by X-rays as 33 *R* (Ramsdell's symbol).

Frank[4] has shown that when growth spreads from an isolated pair of dislocations, respectively right- and left-handed, the terrace line connecting them wraps around and meets itself on the other side: thus forming a short connecting terrace line again and an outward growing closed loop. Such an interaction has been exemplified on silicon carbide[5]. If these two dislocations are cancelled by moving together, as suggested by Mott[6], or by a process of double cancellation, as envisaged by Anderson and Dawson[7], flat-topped crystals would result. Fig. 2 is, however, an example of a flat-bottomed crystal. The

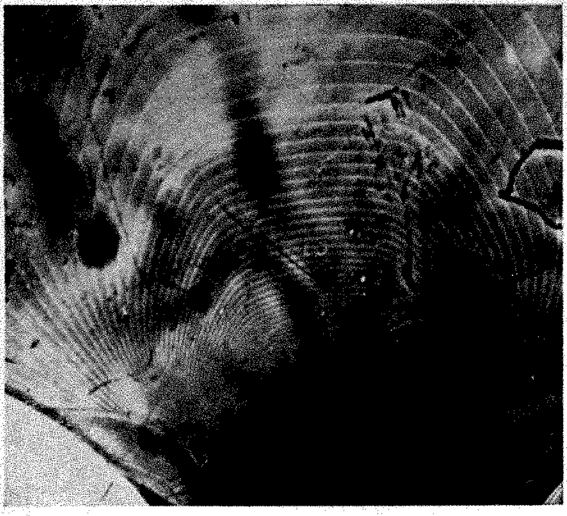

Fig. 1. Spiral pits on silicon carbide. (× 90)

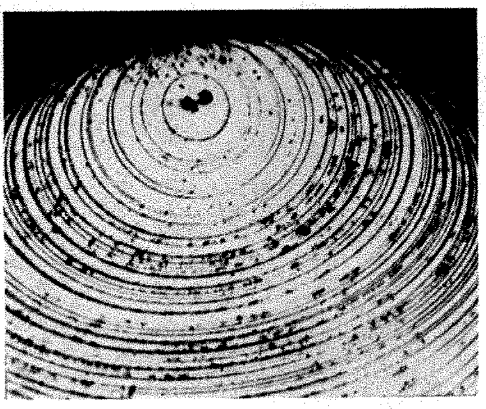

Fig. 2. Spiral pits on silicon carbide. (× 105)

fringes of equal chromatic order passing over the centre of the pit show beyond doubt that it is a pit having a step height of 1050 A.

Such spirally terraced pits are not foreseen as a growth feature on Frank's theory, which envisages spiral pits as a result of dissolution or evaporation. These observations, in conformity with Frank's prediction, suggest that evaporation also takes place in accordance with the dislocation mechanism.

My thanks are due to Prof. S. Tolansky for his kind interest and encouragement and to the Government of India for the award of a Modified Overseas Scholarship, during the tenure of which this work was done in the Physics Department, Royal Holloway College, Englefield Green, Surrey.

Width of the Green Mercury Line from a 198-Isotope Lamp

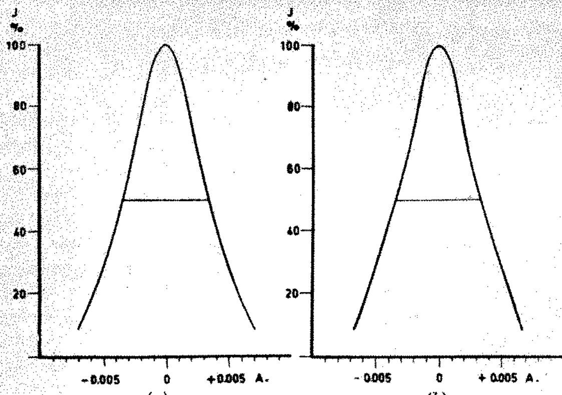
In recent years the mercury isotope lamp has been found most useful and convenient for producing fairly bright and extremely sharp emission lines for spectroscopic purposes. Only a fraction of a milligram of mercury-198 is needed for a discharge lamp of this kind, and this isotope can now be produced quite cheaply from gold. This light source has with good reason been proposed for use as a primary standard of wave-length[1].

Recently, Baird and Smith have pointed out[2] that in certain circumstances, depending on the carrier-gas and on the temperature, asymmetrical self-reversal may occur in such lamps, with a disturbing effect on both the line-width and the wave-length. They have also made useful suggestions as to how this self-reversal can be reduced, by the use of molecular carrier gases such as hydrogen and nitrogen[3].

As very little information has been published about the line-widths or the long-term behaviour of such lamps under ordinary laboratory conditions, the following remarks may be useful. The lamp under consideration was bought in 1951 from the General Electric Co., Ltd.[4], being one out of their serial production. It is a water-cooled internal-electrode discharge lamp; its positive-column tube has a length of about 40 mm. and an internal diameter of about 5 mm., with a coaxial water-jacket sealed around it. The lamp contains about 0·1 mgm. of mercury-198, with argon as a carrier-gas under a pressure of about 10 mm. of mercury. It is usually run from a mains transformer at a current of 25 m.amp., striking at about 500 V. and running normally at 200 V. If necessary, it can be operated from a 6-V. or 12-V. battery using a conventional d.c./a.c. converter. Cooling with water at temperatures of 10–20° C., a flow of about 1 litre in 6 min. was found to be quite sufficient. Should no running water be available, as, for example, under certain field conditions, it is quite possible to maintain a water circulation by hand from a small storage vessel. This particular lamp has now worked for several hundred hours over a period of seven years, mainly for calibrating line-widths with interferometers and large spectrographs. It has also been used by three astronomical research expeditions under very primitive field conditions[5].

The line-width for the green mercury line 5461 A. was measured some time ago with a high-quality Fabry–Perot interferometer of the multicoated type. Its crystalline quartz flats were figured to 1/40 λ and were coated with four quarter-wave layers of zinc sulphide and three quarter-wave layers of cryolite[6]. The reflectivity was at least 95 per cent; the 0·75-cm. spacer consisted of fused silica, giving a range of about 0·170 A. in air, with a resolving power not far from 10^6. In order to improve the resolving power, only a small area, 5 mm. × 7 mm., of the interferometer was used. Using a 'Tessar' lens of 50-cm. focal length to produce an image, exposure times of about 10 min. were needed on Kodak *I–G* spectral plates. The first twelve fringes were measured both by a micrometer and also by a recording microphotometer using a slit width of 0·01 mm. The line profiles of the second and third fringes are reproduced in Fig. 1 on a true intensity scale, derived from the intensity marks available for the plates.

Although these profiles are not intended as high-precision photometric data, they may give useful



(*a*) (*b*)

Fig. 1. Width of the green line of a mercury-198 lamp determined from the second (*a*) and third (*b*) fringes in a Fabry–Perot interferometer

indications of what to expect with a lamp of this kind under normal working conditions. No indication of self-reversal can be detected. However, the thickness of the discharge column was only about 5 mm. (giving quite sufficient light for most purposes) and water-cooling was used, so that the conditions were different from those reported in ref. 2. The half-width was found photometrically to be about 0·006–0·007 A., while the widths of the fringes measured by micrometer were found to be slightly smaller. Such a width is scarcely attainable so conveniently from any other light-source, and it is sufficiently small for investigations even with very powerful spectrographs. Moreover, this may not be the minimum width attainable since the values found here are restricted by the resolving power of the interferometer used, for which a longer spacer was not available. The real line-widths are probably very near the Doppler widths which, at room temperature, should be about 0·0055 A.

A New Microwave Mixer

THE Hall effect in semi-conductors has been used at microwave frequencies for the measurement of power. It has recently been demonstrated that a simple modification to the power-measuring equipment leads to a mixer. The principle of operation of this mixer is straightforward. A local oscillator is used for establishing a field in a resonant cavity and a small piece of semi-conductor is placed at a point in this cavity where there is maximum magnetic field and no electric field. The semi-conductor is coupled to a second wave-guide carrying a microwave signal, the coupling being effected by a probe which causes a current to flow in the semi-conductor; the direction of the current is selected to be at right angles to the local oscillator magnetic field. Since the signal is coupled to the semi-conductor by electric field, whereas the local oscillator field at the semi-conductor is magnetic, there is no interaction between the local oscillator and signal channels. A Hall electromotive force is established, the instantaneous value of which is proportional to the product of the local oscillator magnetic field and the signal current. This electromotive force has therefore components of frequencies equal to the sum of the local oscillator and signal frequencies and to their difference. The latter signal can be amplified as in a normal mixer.

This form of mixer has been examined with a signal of approximately 8 cm. wave-length, giving an output of 60 Mc./s., and it has been confirmed that the mixing operation described above does take place. A simplified theoretical analysis shows that the conversion efficiency of the mixer is independent of the semi-conductor dimensions and is directly proportional to both the local oscillator power and to the square of the electron mobility in the semi-conductor, assuming that this is an *n*-type material. The output power from the mixer is proportional to the signal power provided that the signal power dissipated in the semi-conductor does not cause an appreciable temperature rise. The conversion loss is rather high, being about 60 db. for indium antimonide with a local oscillator power of 100 watts at 8 cm. This figure is based on calculations; experimental results using germanium appear to be in reasonable agreement with the theory.

The present conversion loss is much too high for the mixer to be of practical value in receiver design, but it is hoped that lower figures can be achieved with more efficient design of the local oscillator cavity and for higher frequencies. The main interest in the mixer at present is that it can be developed to provide a method for measuring mobilities at microwave frequencies.

Germanium Enrichment in Lignites from the Lower Lias of Dorset

CERTAIN carbonaceous inclusions from the United States are exceptionally rich in germanium[1,2]; hitherto no such enrichment has been reported from the British Isles. A number of lignite specimens recently collected from the Lower Lias of Dorset have now been shown to have similar concentrations of germanium to those of the American samples.

The Lower Lias of Dorset consists of a series of marine shales and marls and subsidiary limestones attaining a thickness of about 170 m. Details of the succession, which is well exposed on the coast around Lyme Regis and Charmouth, are summarized by Arkell[3]. Scattered throughout these beds are fragments of lignite. The lignite is more common at certain horizons, for example, 'Grey Ledge' at the top of the Blue Lias and the 'Woodstone' of the Black Ven Marls. It is never easily detected in the cliff section, but may be found quite readily on the foreshore. Specimens of lignite embedded in several types of rock were collected from a 5-mile stretch of the coast centred about Lyme Regis. These specimens were mostly a few cm. long and varied in thickness from 4 to less than 1 cm.

The lignites may be grouped into two main varieties termed 'wood-like' lignite and 'jet'. The former is brown and fibrous and is frequently enveloped and intersected by veins of calcite or barite. Wood-like lignite is found in the form of rafts lying parallel to the bedding plane, and as cylindrical 'branches' enclosed in boulders. Occasional giant specimens of up to 3 m. long have been reported (Lang, W. D., private communication). The jet is black and possesses a vitreous lustre on freshly fractured surfaces, which are often conchoidal. Calcite and barite veins are generally less conspicuous. Jet is sometimes found associated with larger bodies of wood-like lignite; but in general, small, isolated samples of jet occur as lenticles parallel to the bedding plane. Microscopic examination of thin sections has shown that the wood-like lignite is composed of thick-walled tracheid cells infilled by calcite. In most specimens of jet, on the other hand, cell structure is completely obliterated, although in some cases partly preserved bordered pits and thin-walled cells infilled by red-brown structureless carbonaceous matter have been observed.

The germanium in the lignites has been determined by spectrographic analysis of their ashes. The ash contents of the lignites varied from about 5 per cent for some of the jet specimens up to 90 per cent for the highly mineralized samples. In 10 of the 29 samples examined, germanium concentrations in the ash exceeded 1 per cent, while concentrations approaching 1 per cent in the whole lignite were found for several samples. The mean concentration for the lignites is about 300 times the mean value for British coals. The results are summarized in Table 1.

Table 1

	Germanium (per cent)	
	Ash	Lignite
Maximum concentration	8·4	0·93
Minimum concentration	0·026	0·024
Mean concentration	1·48	0·18

The jet usually contained higher concentrations of germanium than the wood-like lignite. However, when the concentrations were expressed in terms of the carbonaceous portion of the lignite, the mean values for jet and for wood-like lignite were found to be not significantly different. In contrast to the high concentrations in lignites, the germanium contents of the parent rocks were of the order of a few p.p.m. only. The mean values for shale, marl, limestone and pyrite were 1·7, 2·5, 3·9 and 2·4 p.p.m. respectively. No correlation was found between the germanium contents of the lignites and those of their parent rocks.

There is little doubt that the lignites originated as coniferous driftwood which sank to the bottom of the Liassic sea in a water-logged condition. The wood probably became buried before it reached an advanced stage of decay. The results of the microscopic examination show that the differences between the two varieties of lignite developed during diagenesis. Thus driftwood enveloped in limestone became mineralized by the crystallization of calcite within the tracheid cells and gave rise to wood-like lignite. In marl and shale, however, calcite mineralization was limited and the cell structure progressively replaced by colloidal organic matter, the eventual product being jet.

It is unlikely that the wood from which the lignite originated was highly germaniferous. The element was probably introduced subsequent to the burial of the driftwood. If the enveloping sediments had access to a suitable reservoir of germanium, the element could be brought into contact with the organic material by means of circulating solutions and accordingly adsorbed by the carbon. The observation that both varieties of lignite have similar germanium concentrations relative to carbonaceous matter supports the idea that germanium is associated with this portion of the lignite. It is probable that the small size of the lignite inclusions was conducive to their germanium enrichment. Thin seams of carbonaceous material have been reported by several workers[2,4–6] to be abundant in certain trace elements. It was found that some of the Lyme Regis lignites also have revealed exceptionally high contents of other trace elements in addition to germanium; namely, vanadium and titanium. Since these latter two elements, like germanium, are likely to occur as anions in ground solutions, their abundance in lignite may be partly attributable to preferential adsorption of negative ions by the carbonaceous material.

Twining of the Hop (*Humulus lupulus* L.)

CASUAL observations made by me on the twining of the shoots of the hop suggested that in the first phase of growth (in which the stem extends rapidly and the laterals remain suppressed) the angle made by the gyres of the helix with the horizontal varied with the diameter of the support.

In 1957, experiments were made upon the shoots arising from four sets of Fuggle *N*, a cultivated variety, to determine whether there was a strict relationship between these two quantities. The main crop of shoots appearing above ground in early spring was made to climb vertical rods of different diameters to a height of about 6 ft. Four of the rods consisted of three equal sections of different diameters, two with the broadest portion at the base and two with the narrowest. The remainder of the rods were uniform. Above the rods the shoots were allowed to tangle together and their climbing behaviour was not studied. Only in one shoot was there an outgrowth of the lateral buds, and this was confined to the upper portion of the rod.

The shoots, which ascended the rods very rapidly once twining began, formed almost uniform helices, as the small range in the size of the angle formed

Table 1

Radius of support (1 unit = 1/16 in.)	No. of observations	α Range (deg.)	Mean (deg.)
2	5	69·5–74·0	70·8
3	6	64·5–72·0	68·2
3 (Late stem)	4	61·0–67·5	63·9
4	8	63·5–71·0	66·8
5	9	60·0–67·0	62·1
8	3	49·5–57·0	54·3
8	3	56·5–57·5	57·2
16	1	42·0	42·0
16 (Lateral buds growing out)	1	52·0	52·0
24	1	20·0	20·0

with the horizontal (α) in a vertical series of readings along one rod will show (Table 1). Each stem can therefore be considered as describing a simple helix on a circular cylinder cutting the generators at a constant angle. The radius of curvature of such a helix (R) is related to the radius of the cylinder (a) according to the equation

$$R = a\sec^2\alpha$$

where $(90° - \alpha)$ is the angle with the generators and α the angle made by the tangent to the helix with the plane perpendicular to the axis of the cylinder[1].

The fact that the steepness with which the stem of the hop twines diminishes with increasing diameter of the support suggests that the radius of curvature of its helix may remain constant. We should then expect a straight-line relationship between the radius of the support and the square of the cosine of the angle at which the stem climbs. This line should not pass through the origin, but cut the a-axis at a negative value equal to the radius of the shoot, since we must consider the helix as being described by the longitudinal axis of the shoot upon the surface of a cylinder the radius of which extends to this axis. The results of eight series of observations show that the expected proportionality does in fact exist (Fig. 1). Owing to shoots catching and transferring themselves to adjacent rods in the experiment, only one grew up the whole length of one of the rods of varying diameter. The values given by it fall into alignment with those of shoots climbing uniform rods or portions of rods. A line fitted by eye to the points cuts the co-ordinate axis 1·2 units below the abscissa, a value of the same order as half the diameter of a hop stem.

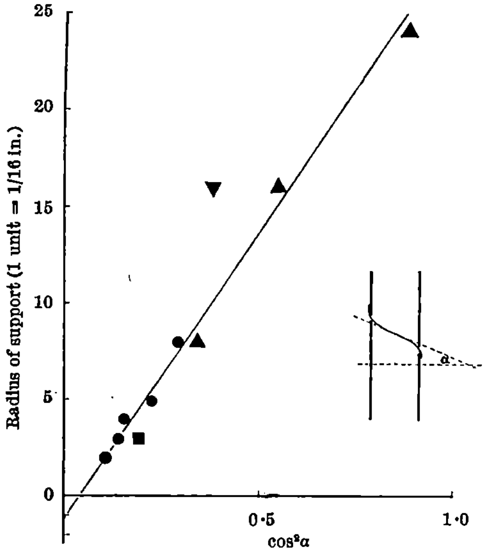

Fig. 1. ▲, Values given by one stem climbing a rod of sections of different diameter; ▼, a stem in which the lateral buds had grown out; ■, a stem ascending after the first flush

These observations agree with Darwin's contention that the twining of the hop is brought about by a wave of growth travelling around the shoot in the extending region[2]. It follows that the intensity of this wave, which will determine the curvature of the helix, is independent of the diameter of the support and consequently must be a property of the stem. It is difficult to decide whether or not the steepness at which the stem twines affects the position of the apex in relation to gravitation, since the upper 6 in. or so of the stem show constant and wide circumnutation, but it can be said that any difference is slight. It is conceivable, therefore, that the gravitational stimuli received by the apex are not affected by the position assumed by the lower regions. A constant curvature in the region of most pronounced internodal extension, where alone the stem first applies itself closely to the support, could then be brought about entirely by an area of vigorous auxin production revolving around the apex as it grows. A comparison of the parenchymatous cells of the cortex on the convex and concave sides of a short median section taken in the plane of the curvature from a stem climbing a support ⅜ in. in diameter showed that the ratio of their lengths was of the same order as would be expected were the curvature attributable entirely to differences in cell elongation (Table 2). This is in conformity with the above hypothesis, but it could also result from a lateral displacement of auxin, such as may occur in haptotropism. Haptotropism by itself, however, could not account for the twining, nor for the constant curvature of the helix.

Table 2. TWENTY-TWO CELLS TAKEN FROM EACH SIDE

	Mean length (μ)	Ratio Observed	Ratio Expected
Convex side	27·7	1·15	1·13
Concave side	24·9		

Only one stem continued to twine around a support three inches in diameter. Others came away from the support after beginning to twine, suggesting that as the radius of the support approached the radius of curvature of the helix the twining system became unstable. One record from the upper part of a stem which had entered the phase of growth in which the laterals grow out is included in Fig. 1. The outgrowth of laterals appears to be accompanied by a diminution in the curvature of the main axis. One of the weaker shoots arising later was also included in the experiment, and the mean curvature of its helix is seen from the results to have been greater than that of a shoot of the first flush.

Further experiments on this and other twining plants are planned.

Relationship between *Merulius lacrymans* and *M. himantioides*

The relationship between the brown-spored species under *Merulius* is not certainly known. The two species, *M. lacrymans* (Wulf.) Fr. and *M. himantioides* Fr., are regarded by Cooke[1] as morphologically alike but distinguishable on the basis of physiological activity and habitat. He therefore considers them as varieties under the same species. He has, however, stated that "more than one species may be indicated if unsuccessful monospore culture pairings are used as indicators of specific barriers". This criterion is used for studying the relationship between *M. lacrymans* and *M. himantioides.*

M. lacrymans was collected from wood of *Pinus sylvestris* in buildings in Denmark at Kibaek, Jutland and at Copenhagen. The latter collection was flown over to Dehra Dun for study. In both our Institutes, the fungus was brought to polyspore and monospore cultures. The spores germinated within 12–15 days after they were planted on 2·5 per cent malt agar at *p*H 5·0 at 18° C. During germination, the spore usually put out a vesicle which finally produced a germ tube. Clamp connexions, which were common in the polysporous mycelium of *M. lacrymans*, were absent in the monosporous mycelium of the fungus, in the hyphæ of which simple septa were present. When two compatible monospore mycelia were paired, clamps developed on the mating hyphæ. In incompatible matings, clamps did not develop. By pairing the monospore mycelia in all possible combinations, they were found to fall into four sexual groups. *M. lacrymans* was thus found to be heterothallic and tetrapolar.

M. himantioides was collected from the open forests in the Western Himalayas (above 6,000 ft.) in India growing on bark of conifers (*Cedrus deodara* and *Picea morinda*). In Denmark, the fungus was collected from floor boards of pine (*P. sylvestris*) in a house at Hundested, North Sealand. Polyspore and monospore cultures of the fungus were obtained from fruit bodies collected from both localities. Germination of spores occurred freely within two days on 2·5 per cent malt agar at *p*H 5·0 at 18° C. On germination, the spore put out a germ tube directly. In this it differed from *M. lacrymans*, where the spore usually germinates by production of a vesicle. In *M. himantioides*, the single-spore cultures did not possess clamps in the hyphæ, which occurred only in polyspore cultures. The spores fell into four sexual groups, and the fungus is heterothallic and tetrapolar.

Crosses were then made between the monospore cultures of *M. lacrymans* and *M. himantioides* by pairing the four sexual strains of the former with those of the latter in all possible combinations. In this test, the Jutland and Copenhagen collections of *M. lacrymans* were paired respectively with North Sealand and Indian collections of *M. himantioides.* Clamps did not develop in any of the pairings, proving that the two fungi are mutually intersterile.

M. lacrymans differs from *M. himantioides* in habitat, the former being usually domestic and the latter wild. The two fungi also differ in the morphology of the sporophore and in culture, particularly in the texture and colour of the mat and formation of profuse liquid drops in *M. himantioides* and their absence in *M. lacrymans.* In culture the optimum growth of *M. lacrymans* occurs at about 18° C., while with *M. himantioides* it is at about 28° C., at which *M. lacrymans* ceases to grow. These differences are believed to be sufficiently diagnostic for identifying the two fungi as distinct species, and this is confirmed by genetic studies as reported above. A detailed account of this work will be published later.

Occurrence of Spermatophores in the Genus *Dolops* (Crustacea : Branchiura)

According to all those who have defined the group, one of the diagnostic characteristics of the Branchiura is the absence of spermatophores. Indeed, the mating habits of members of the genus *Argulus* are sufficiently well known to enable it to be stated that here no such structures are involved in sperm transfer, and recent unpublished observations on various species of the genus *Chonopeltis* (some as yet undescribed) indicate that here also no such structures are found. On the other hand, the existence of spermatophores in the genus *Dolops* has recently been established.

These structures were first observed in Africa during the course of an examination of specimens of *Dolops ranarum* (Stuhlmann), which is the only known African representative of an essentially South American genus. Later, when an opportunity was taken to examine the rather small collection of South American species of *Dolops* in the British Museum (Natural History), a single female of *D. geayi* (Bouvier) was found to be carrying a spermatophore, thus suggesting that the employment of these structures may be a regular feature of the reproductive process throughout the genus.

The following remarks apply particularly to *D. ranarum* ; but the spermatophore of *D. geayi* appears to be essentially similar to that of its African relative.

Spermatophores, which bear a most striking resemblance in form, colour and lustre to pearls, are attached singly in the mid-ventral line of the female at the base of, and just behind, the fourth pair of legs. Their size appears to vary according to the size of the male which produced them, and possibly according to other and, as yet, unknown factors. The length of the longest axis of these subspherical structures may be as much as 560μ.

Transference of spermatophores from male to female has been observed, and is a relatively simple process, as might reasonably have been inferred from the almost complete lack of accessory copulatory organs in *D. ranarum*, which contrasts strongly with the presence of extremely complex organs in the males of all known species of *Argulus* and *Chonopeltis*.

While the purpose of this communication is essentially to announce the discovery of spermatophores, a note of caution must be sounded to those who would cite their existence as evidence of a close relationship of this taxonomically enigmatical group to the Copepoda. It is true that the possession of spermatophores by *Dolops* suggests that the Branchiura is quite distinct from the Branchiopoda with which some would group it. On the other hand, however, spermatophore formation need not necessarily represent the retention of a characteristic exhibited by a possible common ancestor of the Copepoda and Branchiura. It could equally well be a device which has arisen independently in the genus *Dolops* in order to facilitate successful sperm transfer in the absence, in some species at least, of the complex accessory copulatory organs found in allied genera. Preliminary observations indicate that spermatophore formation in *Dolops* involves processes which are unknown in any of the Copepoda. It is hoped to pursue these studies further in due course.

Ironically, although spermatophores are reported here for the first time, they were in fact unwittingly mentioned more than sixty years ago by Stuhlmann[1], who described *D. ranarum*, and reported that "oft sieht man an der Geschlechtsöffnung des ♀ ein rundes, weisses Ei". What Stuhlmann took to be an egg was in fact a spermatophore.

Retinal Pigments of a Labrid Fish

The distribution of visual pigments in aquatic vertebrates has been assumed to follow this pattern[1]: marine fishes possess rhodopsin ($\lambda_{\max.}$ 500 mμ), based on retinene$_1$, and freshwater fishes possess porphyropsin ($\lambda_{\max.}$ 522 mμ), based on retinene$_2$. Since the report by Wald[1] that labrid fishes have porphyropsin, the members of this family of marine teleosts have been regarded as exceptions to the general picture of visual pigment distribution. It should be made clear, however, that Wald did not study the visual pigment itself in the Atlantic species, *Tautoga onitis* and *Tautogolabrus adspersus*, which he examined, but based his conclusions on an analysis of the retinal vitamin A. Confirmation was reported by Kampa[2] for two unspecified corid (labrid) fishes in the Caribbean. She apparently studied the visual pigment, retinene and vitamin A, but only summarized her findings and has not published the full results. More recently, in a brief abstract[3], Wald has stated again that *Tautoga* possesses porphyropsin.

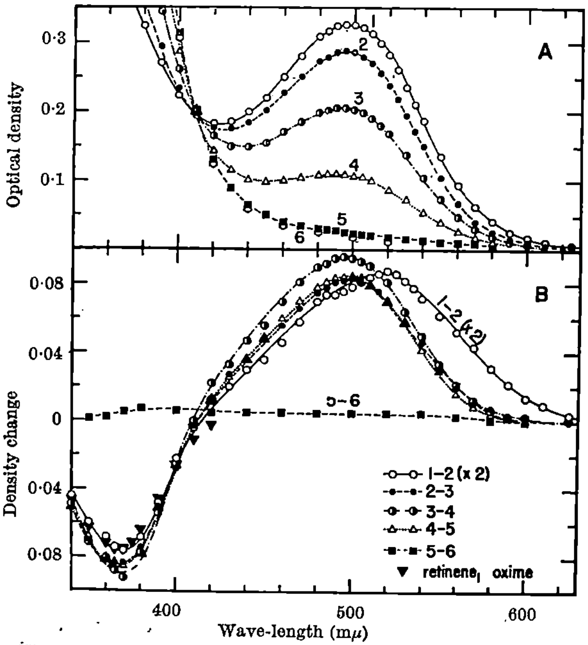

Fig. 1. *A*, Partial bleaching experiment. Curve 1, absorption of unbleached extract; curve 2, after 80-min. exposure to 650 mμ light; curve 3, after 20-min. exposure to 605 mμ light; curve 4, after 45-min. further exposure to 605 mμ light; curve 5, after 75-min. exposure to 590 mμ light; curve 6, after 10-min. exposure to white light. *B*, Difference spectra of partial bleaching experiment. Curve 1–2 (drawn to × 2 scale) is the result of the 650 mμ bleach, 2–3 and 3–4 the 605-mμ bleaches, 4–5 the 590-mμ bleach, and 5–6 the white light bleach. The inverted triangles are spectral densities of a digitonin solution (*p*H 8·3) of retinene$_1$ oxime scaled for comparison with curve 1–2

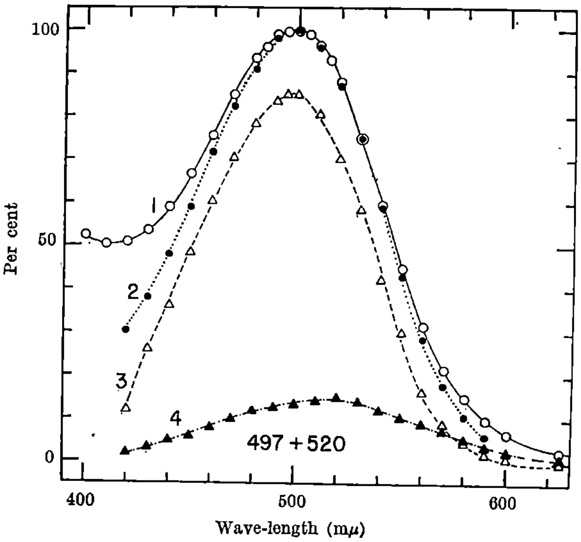

Fig. 2. Curve 1, absorption of unbleached extract; curve 2, constructed from Dartnall's nomogram, assuming $\lambda_{\max.}$ 500 mμ; curve 3, difference spectrum of red-insensitive component; curve 4, difference spectrum of red-sensitive component. Curves 3 and 4 scaled so as to approximate in sum the total difference spectrum

The sheep-head, *Pimelometopon pulchrum* (Ayres), is a labrid of the eastern Pacific. Over the last 30 months, four digitonin extracts of the retinæ of this species (gratitude is expressed to Marineland of the Pacific for the specimens used in this study) have been prepared and analysed by methods described elsewhere[4]. The results have been consistently the same: the chief photosensitive retinal pigment of the sheep-head is a retinene$_1$ pigment with $\lambda_{\max.}$ 497 mμ. In addition there is a small amount of another retinene$_1$ pigment with $\lambda_{\max.}$ 520 mμ. These two photolabile components were present in the extracts in the ratio 85 : 15. This mixture was disclosed by partial bleaching experiments without hydroxylamine (not figured) and with it (Fig. 1). Exposure to deep red light selectively removed the red-sensitive component (curve 1–2). Further exposure to non-isomerizing light of shorter wave-lengths then bleached the main photolabile component (curves 2–3, 3–4, 4–5).

The product of bleaching of both components is characteristic of retinene$_1$ pigments. In Fig. 1*B* the absorption spectrum (inverted triangles) of retinene$_1$ oxime (prepared from crystalline all-trans retinene$_1$) is plotted for comparison with the bleaching product of the red-sensitive component. In experiments without hydroxylamine the spectral position of the alkaline indicator yellow also suggested that retinene$_1$ is the chromophore. Neither light-sensitive component in the sheep-head retina, therefore, can be termed a porphyropsin.

Comparison of the absorption of the unbleached extract (Fig. 2, curve 1) and the nomogram construct[5] (curve 2) for a visual pigment with $\lambda_{\max.}$ 500 mμ shows that the nomogram curve is not broad enough to match the retinal extract. This suggests a mixture of components, confirming the result obtained in bleaching experiments. The hydroxylamine difference spectra (curves 3, 4) of these pigments are shown in about the proportion that they are present in retinal extracts.

It is clear that these results do not confirm the general statement of Wald[1] that the Labridae possess porphyropsin. In the sheep-head, at least, there are two pigments, one very similar to lamprey visual purple[6], the other to the visual pigments of geckos[7]. Whether the red-sensitive component of *Pimelometopon* is a cone pigment or a secondary rod pigment cannot be decided from the present observations. Unlike chicken iodopsin[8], the red-sensitive pigment of the sheep-head is stable under alkaline conditions and in the presence of hydroxylamine. It would be very desirable to re-examine the Atlantic labrid fishes to determine whether they really do have porphyropsin and whether this marine family is split into two groups, those with retinene$_1$ photopigments, and those with retinene$_2$ pigments.

Effects of Ultra-Violet Radiation on Oysters

It seemed of value to examine the influence of ultra-violet light upon the rate of cleavage of artificially fertilized eggs of *Crassostrea angulata* L., the larvæ of *Ostrea edulis* L., as well as their adults. The oysters were collected in the summer of 1956 from their natural beds in south Brittany. The experiments were undertaken partly in the Auray Bacteriological Laboratory, and partly in the Arago Laboratory at Banyuls-sur-Mer. A wavelength of 3600 A. from a quartz mercury arc was used.

The gametes and the fertilized eggs of *C. angulata* were irradiated with graded doses up to 30 min., with the ultra-violet source 50 cm. above the water level. The sperms were found to be more resistant than were the eggs. After doses longer than 5 min., there was a pronounced reduction in the rate of cleavage; when the controls had reached the second cleavage stage, some of the eggs irradiated for 10 min. had not completed the first stage. Later, when 100 per cent of the controls had developed into ciliated trochophores, some of the irradiated eggs were still in the first, second and third cleavage stages and only 5 per cent had developed into free swimming blastulæ. With still stronger doses of 20–30 min., 10 per cent of the eggs developed into balls of motile cells, and 90 per cent remained with the germinal vesicle intact.

Normally, the newly hatched larvæ of *O. edulis* manifest positive phototropism and negative geotropism. When irradiated for 5–7 min. in a container 1 m. deep, with the ultra-violet source 35–125 cm. above the water surface, they showed a tendency to occupy the lower levels in the aquarium and finally to stop swimming freely and to settle down near the bottom with their shells almost closed. Evidently, it was a temporary tropistic response to avoid injury, as many were noticed, later, to regain their activity and to swim freely again. The percentage of larvæ recovered and the time of recovery depend largely upon the strength of the dose.

An exposure of 15 min. from a source at 35 cm. above the surface of water only 20 cm. deep was lethal. The ultra-violet effect was, however, eliminated when, in a new experiment, a glass plate was placed between the larvæ and the ultra-violet source, showing that the larval shell was not adequate protection against strong doses.

The adult *C. angulata* and *O. edulis* were found to resist strong doses of 30–60 min. with the source 35–50 cm. above the surface. All the oysters survived normally for the next two months, and some even showed a slight growth. Many of the parasites which happened to live on their shells were killed by the irradiation.

The radiosensitivity of many planktonic organisms, including some oyster enemies, was found to vary widely in the different forms. While worms like *Polydora*, bacterians and some fungi were highly susceptible, crustacean larvæ and copepods proved to be less sensitive.

In brief, the main conclusions are: 1, the cleavage of artificially fertilized eggs as well as the development of later stages of *C. angulata* is considerably retarded after irradiation; 2, the results of irradiating *O. edulis* larvæ help to explain—in the light of studies on solar radiation and its transmission through air and water—the variations noticed every year in the density of oyster spat setting at different levels on natural and artificial collectors; 3, the resistance of the animal, regardless of its size, depends upon the nature of its outer surface, its thickness, and the strength of the dose; 4, a great progress in artificial propagation of oyster culture would be achieved by discovering some control method involving the use of ultra-violet doses not harmful to the oysters, their larvæ, or feeding organisms, but destructive to the enemies which compete with them for food and space.

Although the practical application of such methods to natural shellfish grounds would be very difficult, I think they might be used on the small isolated bodies of water used for rearing oyster larvæ artificially and for growing their food cultures.

My special thanks are due to Prof. G. Petit, director of the Arago Laboratory, and to M. L. Marteil, chief of the Bacteriological Laboratory at Auray, for the many courtesies extended to me during my work in France.

Labelling of Bull Semen with Phosphorus-32 *in vivo*

Recent work has indicated that when rams are injected intravenously with labelled phosphate and serial samples of semen collected, the various phosphorus components of the semen appear with maximal radioactivity in a definite time sequence[1]. In this communication these experiments have been extended to a bull, both with the view of obtaining information about various physiological processes in its reproductive tract and also for acquiring labelled sperm for other experimental purposes.

A Shorthorn bull (780 kgm.) was injected intravenously with 14 ml. isotopic saline containing 25 mc. labelled phosphate through a cannula inserted into the jugular vein. Semen samples were collected twice a week using an artificial vagina. The sperm were examined throughout the investigation for motility, morphological appearance and density, and no indication of any change became apparent. This showed that the testes cannot have suffered any gross radiological damage due to the administration of the isotope. The sperm and seminal plasma were then separated by centrifuging and the following fractions isolated and assayed for radioactivity and phosphorus: sperm acid-soluble phosphorus, phospholipids, deoxyribonucleic acid and residual phosphorus (Schmidt and Thannhauser[2], phosphoprotein + ribonucleic acid); seminal plasma glycerylphosphorylcholine and total phosphorus. The methods used for fractionation and analysis have been described previously[1]. However, due to the presence of considerable mucoprotein in bull seminal plasma compared with that of the ram, it was necessary to modify the procedure for the isolation of glycerylphosphorylcholine as follows. The seminal plasma (3–4 ml.) was treated with 7 ml. ethanol, centrifuged and the supernatant taken to dryness *in vacuo*. The residue was extracted with 10 ml. ethanol and the ethanol-soluble substances then partitioned between water, chloroform, butan-2-ol and chromatographed as described for the ram.

In Fig. 1 is illustrated the pattern of activity appearing in ejaculates collected over a period of 70 days. The seminal plasma glycerylphosphorylcholine acquired maximal activity in samples obtained 11 and 14 days after isotope injection and then its radioactivity slowly declined. The peak of its activity arrived before the activities of any of the sperm components appeared with maximal activity which is consistent with observations made upon the ram, and the conclusion that the source of semen glycerylphosphorylcholine is largely in the epididymides[1,3]. It is interesting that the specific radioactivity of the seminal plasma total phosphorus fraction closely followed that of the glycerylphosphorylcholine. Although this phosphodiester would be the major component in the seminal plasma phosphorus fraction, it is surprising that there is no evidence of an ejaculation of highly active phosphate immediately after the isotope administration or contamination of the semen with highly active urine phosphate. This is possibly because the injected labelled phosphate rapidly disappears from the blood stream and that equilibrium conditions are established long before the first semen sample was collected, that is, 4 days after the injection.

The sperm phospholipid, residual phosphorus and acid-soluble phosphorus in the ejaculates reached a maximum initial labelling at 21, 18, and 25 days respectively. The acid-soluble phosphorus in the sperm shows some evidence of an exchange with the phosphorus in seminal plasma as there is a distinct kink in the curve at the time when seminal plasma phosphorus shows its maximum specific radioactivity. This probably occurs after ejaculation; Bishop and Weinstock[4] have found, for example, that bull spermatozoa when suspended in saline containing labelled phosphate rapidly acquire radioactivity in their acid-soluble phosphorus fraction.

The main peak in the specific radioactivity time-curve of the sperm deoxyribonucleic acid phosphorus reaches a maximum 60 days after the injection, which compares with a time of 50–52 days found for the ram. Recently, H. H. Koefoed-Johnsen (personal communication), in similar experiments

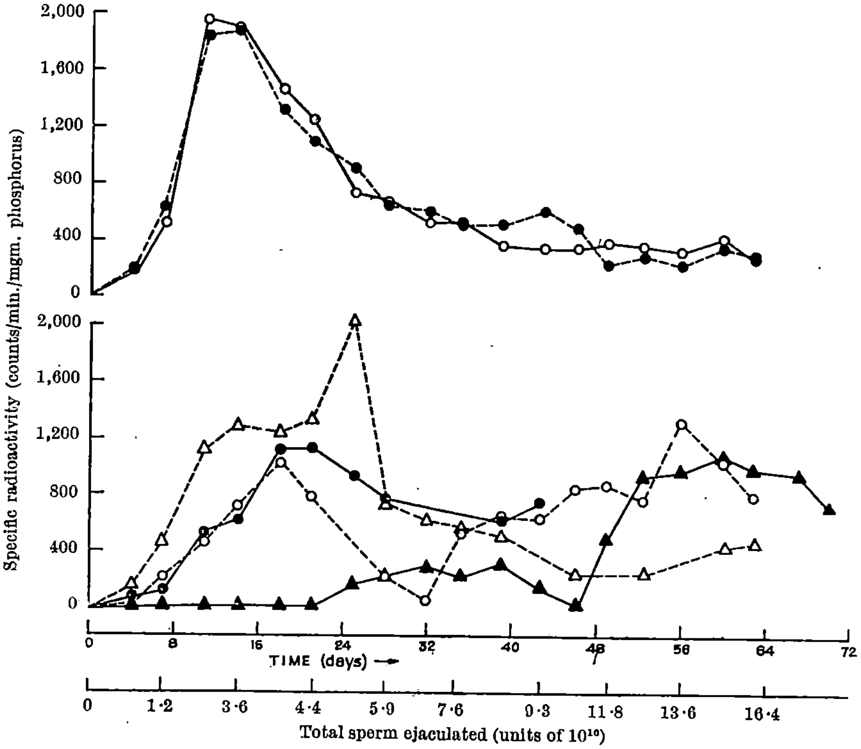

Fig. 1. The appearance of labelled phosphorus components in samples of semen collected from a bull injected with radioactive inorganic phosphate. The abscissa represents the time in days after the injection and on a lower scale is given the total number of sperm ejaculated after the administration of isotope. Upper curves, seminal plasma. ○—○, glycerylphosphorylcholine phosphorus; ●---●, total phosphorus. Lower curves, sperm. ●—●, lipid phosphorus; △---△, acid-soluble phosphorus; ▲—▲, deoxyribonucleic acid phosphorus; ○---○, residual phosphorus

which are as yet unpublished, found that in a bull dosed with labelled phosphate it required some 62 days for the sperm deoxyribonucleic acid to be ejaculated with maximal activity: a value which is in good agreement with the present results. The sperm deoxyribonucleic acid possesses some low activity before the appearance of the main activity peak; such a phenomenon did not occur in the ram and it is consequently difficult to assess its significance from an experiment on a single animal. In the ram it was suggested that the difference between the times of ejaculation of the main sperm phospholipid and deoxyribonucleic acid peaks was due to the fact that while the former would be added or turned over up to the end of spermatogenesis, no new deoxyribonucleic acid would be formed after the mitotic divisions forming the primary spermatocyte. If this explanation is correct, this would mean that in the present experiment the average time for the primary spermatocytes to be converted into the finished spermatozoa would be 39 days.

Bronsch and Leidl[5] have recently found that in bulls given labelled phosphate intramuscularly maximum activity was ejaculated in the semen 14 days after its administration: all the activity being found in the seminal plasma and none in the sperm. The present experiment agrees with these observations in that the seminal plasma total phosphorus reaches peak activity in the 11–14-day period after isotope administration, but shows in addition that at this time a small but significant part of the labelling is present in the sperm and cannot be removed from it by saline washing.

I am indebted to Miss N. Hemington and Mr. R. White for valuable laboratory assistance, and Messrs. Clarke and Wise for assistance in handling the bull.

Glycerol Metabolism of the Brown Rot Mould *Poria vaillantii*

THE characterization of the chemically unchanged lignin of woody tissues requires the removal of the cellulose with which it is associated. The successful utilization of wood-destroying organisms for the isolation of large amounts of enzymically liberated lignin[1] and for the elucidation of the mechanism of the biogenesis of lignin building stones[2–5] prompted an attempt at the isolation of a cellulolytic enzyme from the wood-destroying mould *Poria vaillantii*[6]. During studies of the cultivation of the mould, an attempt was made to use a medium containing glycerol instead of glucose as the sole carbon source, since glucose interferes in the assay of the cellulolytic enzyme which is obtained from the filtrates.

After 4–6 weeks of growth on a glycerol medium, the culture filtrates were collected and found to contain reducing substances. Analysis of the concentrated filtrate revealed the presence of acetaldehyde, dihydroxyacetone, and glucose. Acetaldehyde was identified as its dimedone derivative. The product after three recrystallizations did not depress the melting point of an authentic sample prepared in the same manner. The concentrated filtrate gave positive Seliwanoff and phosphomolybdate tests, indicating the presence of dihydroxyacetone. Glucose was identified by extraction from a paper chromatogram as its 2,4-dinitrophenylhydrazone derivative. There was no depression of melting point of a mixture of this compound and an authentic hydrazone specimen.

A cyclic mechanism, by which glucose could arise from glycerol, was first postulated by Horecker[7].

The identification of the above intermediates in the metabolic filtrates of the mould *Poria vaillantii*, grown on glycerol as sole carbon source, suggests that this cycle may be operative in the metabolism of this organism.

This study was carried out within a programme sponsored by the National Science Foundation and the U.S. Public Health Service.

Breeding of Dragonflies in Temporary Waters

THROUGHOUT Western Australia there are five or more consecutive months in which there is little or no rain. Over the greater part of the State the mean annual rainfall is less than 20 in., derived mainly from a few heavy falls. The surface-waters which result from these rains usually persist for a few months at the most; there are very few permanent, natural fresh waters. In the south-west (as at Perth), the rainfall exceeds 35 in. and is derived from more frequent lighter falls, but even here many of the surface-waters dry up from about November until April or May.

These temporary waters are colonized by many aquatic insects, and several species of both Zygoptera and Anisoptera, although not confined to such places, breed commonly in them. These include five species of *Austrolestes*, *Anax papuensis*, *Hemicordulia tau*, *Orthetrum caledonicum* and *Diplacodes haematodes*.

To breed successfully in temporary waters larvæ must either survive drying or complete their development in six months or less. Although Tillyard[1] found that larvæ of *Synthemis eustalacta* (a swamp species from south-eastern Australia) could withstand drying in sand for four months, there is no evidence that the common species of temporary ponds in Western Australia actually do so. Newly filled ponds have shown only young larvæ, and larvæ at all stages of development have been found dying in large numbers in pools from which the free water has evaporated. However, larvæ do complete development and emerge before the pools dry, and there can be little doubt that these have developed from eggs laid in the previous April or May when the ponds first filled.

These observations have been made in the vicinity of Perth where pond temperatures vary from 40–60° F. in winter, up to 70–80° F. in early summer. Summer water temperatures are probably higher inland, and in the tropics they show a daily range of 75–112° F.

In the laboratory, rearing experiments have been carried out on three Anisoptera of temporary ponds. During these experiments, larvæ were kept in individual containers in circulating water and given an excess of food. At the upper temperature (85° F.) mortality was initially high. The results of the experiments are shown in Table 1.

Table 1. GROWTH OF ODONATA AT DIFFERENT TEMPERATURES

Species	Growth period	Mean duration in days (No. of animals)		
		Outdoors 46–76° F.	70° F.	85° F.
Anax papuensis	Oviposition to hatching		14	
	4–10 mm. larva to emergence (~ 48 mm.)	176 (1)	70 (4)	45 (2)
Hemicordulia tau	Oviposition to hatching	20	10	6
	2–3 mm. larva to emergence (~ 21 mm.)	132 (6)	56 (10)	36 (2)
Diplacodes haematodes	Oviposition to hatching		10	6
	Oviposition to emergence		89 (2)	56 (3)

It is evident that, at the high temperatures found in many shallow ponds, these three Anisoptera can complete their aquatic life well within the time required to make use of temporary waters. Experiments performed by Gardner[2] with *Orthetrum stemmale capense* and *Palpopleura lucia* from Africa gave similar results, and it seems probable that other pool breeders will also show rapid growth rates. By contrast, *Acanthaeshna anacantha*, which breeds in permanent hill streams of the south-west of Western Australia, takes at least one and possibly two years to complete its development. Larvæ of this species have shown retarded growth and extremely high mortality at 85° F. and little or no acceleration of growth at 70° F.

The expenses of this investigation have been met from a University of Western Australia Research Grant. One of us (J. A. L. W.) was in receipt of a Commonwealth Scientific and Industrial Research Organization Studentship.

Occurrence of *Donsiella limnoriae* Stephensen (Copepoda, Harpacticoida) in the Southampton Area

Donsiella limnoriae was first described by Stephensen[1] in 1936 from some 20 specimens which had been found in association with *Limnoria lignorum* at Trondheim, Norway. Since then this species does not appear to have been found again, hence its occurrence in waters near Southampton is of interest. Three females were found on *Limnoria tripunctata* collected at Cowes, Isle of Wight, and three females and two males from *L. quadripunctata* at Calshot. The 'infection' was very low, at least during October when the collections were made. Only three *Donsiella* were taken from 220 *L. tripunctata* from Cowes and five from 69 *L. quadripunctata* at Calshot. While the specimens collected near Southampton could undoubtedly be identified as *Donsiella limnoriae* Stephensen, they show certain differences in structure from the description of the Norwegian specimens.

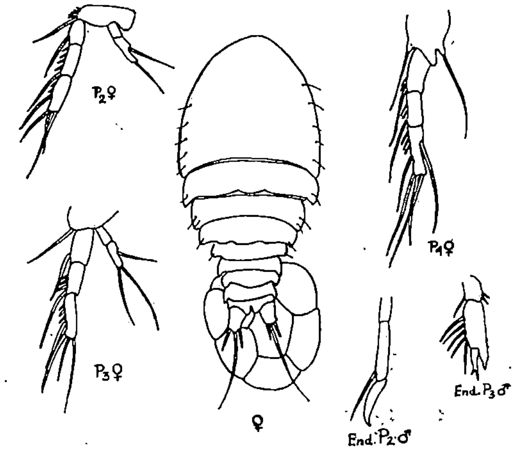

Fig. 1. *Donsiella limnoriae* Stephensen. ♀, Female with egg mass; *P*$_2$♀, *P*$_3$♀, *P*$_4$♀, second, third and fourth leg of female; *End. P*$_2$♂, *End. P*$_3$♂, endopodite of second and third leg of male

The specimens collected here are similar to those from Trondheim in general body shape and size. The structure of the endopod of the second leg, however, exhibits certain differences. It is two-jointed, the terminal joint being only a little longer than the proximal, and carrying only one inner and one apical seta; according to the original description the distal segment is more than twice the length of the proximal and carries one inner and three apical setæ[2]. In the third leg also, the second joint of the endopod is a little longer than the first in the Southampton specimens, whereas it is twice the length of the first joint in the Norwegian specimens.

In the male, the structure of the endopod of the second leg exhibits certain differences from the original description. The endopod is three-jointed, the second joint being longer than the first and carrying an inner seta; the terminal joint ends in a claw-like structure without setæ. In the Norwegian specimens, on the other hand, the terminal joint is shown as having an inner seta and to be nearly twice the length of the middle one. In the endopod of the third leg of the male, the terminal joint is small and narrow, ending in a bifid projection in the Southampton material; in the specimens from Norway, the terminal joint is broad with its outer end produced into a spinous projection and carrying two inner setæ.

When living, these copepods cling to the isopod 'host' with the help of the first leg or crawl about on the surface. They are often found in the spaces between the epimera of the body and the bases of the legs. It is likely that these copepods have been overlooked in the past because of their small size and transparent nature. Perhaps they are more widely distributed than appears from present records. A detailed description will be published when more specimens are available.

We wish to thank Prof. J. E. G. Raymont for several valuable suggestions and Mr. A. R. Hockley for some of the specimens.

Internal Seed Disinfection with Pyridine-2-thiol-N-oxide and a Derivative

Conventional seed disinfectants are unsatisfactory in the combat of internal parasites in seeds because they do not penetrate far enough. Successful disinfection of pea seed carrying the internal fungal parasite *Ascochyta pisi* has, however, been achieved by Dekker[1–3] using the antibiotics rimocidin and pimaricin. Using the same methods and similar material we have now found that the strongly fungicidal agents pyridine-2-thiol-N-oxide and 2-pyridyl-N-oxide-isothiourea hydrobromide are as effective as these antibiotics.

Of pea seeds (variety Eminent) which showed a high percentage of internal infection with *Ascochyta pisi* lots of 25 peas were soaked for 24 hr. in 0, 10, 25 and 100 p.p.m. of pyridine-2-thiol-N-oxide. The seeds were afterwards placed on filter paper. The number of those from which *A. pisi* developed was 17, 3, 1 and 1 respectively. Seeds of another sample were sown in soil after soaking lots of 200 peas in aqueous solutions containing 0, 10, 25, 50, 100 and 200 p.p.m. of pyridine-2-thiol-N-oxide for 24 hr. After 13 days the number of diseased plants emerging from these seeds was 20, 9, 3, 3, 2 and 1 respectively. Germination of the seeds and development of the plants was unimpaired by the pyridine-2-thiol-N-oxide treatment. The effect of this treatment on *A. pisi* is quite clear from these two experiments.

Bean seeds (*Phaseolus vulgaris*) could not be soaked because immersion in water for 24 hr. proved harmful. Thus a slurry consisting of 92 mgm. pyridine-2-thiol-N-oxide, 40 mgm. carboxymethylcellulose and 0·4 ml. water was applied to 80 seeds which were afterwards sown in soil. Emergence of the plants from treated seeds was somewhat slower than that from untreated seeds. After 12 days, however, 54 plants had developed from the treated seeds and of these 2 showed disease symptoms. The 80 control seeds gave rise to 53 plants of which 39 showed *Colletotrichum lindemuthianum* infection.

Treatment of pea seeds with 2-pyridyl-N-oxide-isothiourea hydrobromide proved as good as with pyridine-2-thiol-N-oxide. Lots of 50 seeds were soaked for 24 hr. in 0, 50, 100 and 200 p.p.m. of 2-pyridyl-N-oxide-isothiourea hydrobromide in water and afterwards placed on filter paper. The number of seeds from which *A. pisi* developed was 35, 5, 0 and 0 respectively.

These results suggest that pyridine-2-thiol-N-oxide and 2-pyridyl-N-oxide-isothiourea hydrobromide are able to penetrate into the seeds. This could be confirmed by bioassay of internal parts of treated seed. Slight systemic protection by pyridine-2-thiol-N-oxide has been earlier reported[4] for cucumber seedlings against *Cladosporium cucumerinum* and for broad bean plants against *Botrytis fabae*.

It is possible that the volatility of pyridine-2-thiol-N-oxide facilitates penetration into the seeds. 2-pyridyl-N-oxide-isothiourea hydrobromide is not volatile, however, but it is suggested to give rise to pyridine-2-thiol-N-oxide by hydrolysis under physiological conditions, for it has been found (unpublished results) to have the same fungicidal activity and mode of action *in vitro* as pyridine-2-thiol-N-oxide[5].

The insoluble copper complex of pyridine-2-thiol-N-oxide, which is its actual toxic agent[5], shows no systemic effect on *Ascochyta pisi* in pea seeds, nor does the S-carboxymethyl derivative. This latter compound is not fungicidal *in vitro*, but showed a slight systemic effect when applied to broad bean plants[4].

We are indebted to J. C. Overeem of the Institute for Organic Chemistry T.N.O. for preparing the compounds.

Choice and Application of Fungicides to Plantation Crops, with Special Reference to *Hevea brasiliensis*

It is clear from the correspondence of this Institute during the past two to three years that the extent of care sometimes required in the choice and application of a fungicide to plantation crops is not invariably appreciated. The hazards in the latter case do not necessarily include a significant effect on the ecology of the area, but they do sometimes include a serious effect on the visual or technological quality of the plantations' finished product. This difficulty is encountered with an appreciable number of plantation crops, but it is probably particularly acute in the case of *Hevea brasiliensis* as so many valuable or potentially valuable fungicides are either (*a*) vulcanizing agents or accelerators of the vulcanization of natural rubber, for example, sulphur, which is used in the control of defoliation due to *Oidium hevea*[1], and certain salts of substituted dithiocarbamic acid which are at present under examination for the control of defoliation due to *Phytophthora palmivora*, or (*b*) extremely effective catalysts of the oxidative degradation of natural rubber, for example, copper compounds which have been examined in Ceylon[2] and elsewhere for the control of defoliation due to *Phytophthora palmivora*.

Clearly, the successful use of such fungicides in mature *Hevea brasiliensis* areas requires either the application of the dusting or spraying formulations under conditions where contamination of the product is physically impossible or the collection of data which show that the extent of contamination of the product by the technologically active ingredient is, or can be made, of negligible significance. It has been assumed that when sprays or dusts are used for controlling leaf diseases the major sources of contamination in the field will be (*a*) drifting at the time of application, (*b*) rain-borne contamination arising through water washing down the trunks and (*c*) wind-borne contamination arising through wind, usually with rain, blowing the particles from point to point after application. On the basis of these assumptions, the first criteria mentioned above, namely, application of the fungicide under conditions where contamination is physically impossible, can probably be met either by the employment of, say, voluminous mackintosh-type rainguards which protect appropriate areas of the tree, or by the application of the fungicide at periods when the areas to be treated are out of production. It is now known[3] that rainguards which probably minimize only contamination arising through rain washing down the trunks are not invariably sufficiently effective, and detailed information on mackintosh type rainguards is not yet available.

In the absence of protective devices which preclude the possibility of contamination by the technologically active ingredients of fungicides, the actual and permissible extent of contamination must be considered in detail for each fungicide. However, with the exception of a reference by Petch[4] to a brief experiment with Bordeaux mixture, this Institute is aware of very little published information on the actual extent of contamination found under commercial conditions with fungicides employed against leaf diseases of *Hevea brasiliensis*.

In the case of fungicides based upon copper the permissible extent of contamination must at present generally be regarded as defined by the type descriptions of the Rubber Manufacturers' Association of New York Inc., which contain a clause limiting the total copper content to 8 p.p.m. The corresponding figure for manganese is 10 p.p.m.

Clearly, detailed information on the extent of contamination of processed natural rubber samples by the technologically active ingredient of one type of fungicide is only of value as an indication of the extent of contamination with other fungicides if (*a*) reasonable allowance is made for factors such as the relative proportions of the technologically active ingredients and the presence or absence of sticking and wetting agents, etc., and if (*b*) the annual differences in the climatic conditions of the particular areas involved can be largely ignored. Subject to these and certain other provisos, the information published, or to be published, elsewhere[3,5,6] on the copper content of samples of processed natural rubbers collected over the period 1955–57 from small experimental areas and from areas on commercial plantations which have been dusted with formulations containing 0–6 per cent copper at the rate of 8–16 lb. per acre per round can be tentatively generalized as follows. First, under climatic conditions similar to those found during the Ceylon low country '*Phytophthora* season', fungicides containing an ingredient which becomes of adverse technological significance when present in natural rubber at a concentration of the order of 8–10 p.p.m. should apparently only be used, against leaf diseases of mature *Hevea brasiliensis* in tapping, with very strict care at all stages in the field and in the plantation's factory even when the dusting formulation contains preferably no more than 1 per cent of the technologically active ingredient. Dusts containing 4 per cent of the technologically active ingredient can probably be employed; but the probability that certain batches of the final product may have to be rejected or be submitted to special processes in the plantation's factory appears to be increased. Secondly, in a similar manner it may be reasonable to suggest that where the care which would be taken on the plantation to minimize contamination or the effects of contamination is of an appreciably lower order, 1 or 4 per cent dusting formulations would probably be practicable, provided the relevant ingredient is not of adverse technological significance when present in natural rubber at concentrations below about 25 p.p.m. Thirdly, where the care on the plantation is of a distinctly low order the relevant concentration figure at which significant adverse technological effects are noted should probably be not less than about 220 p.p.m. A further point at present of only local practical interest is that although this Institute at present suggests[2] copper for the control of defoliation due to *Phytophthora palmivora*, it would obviously prefer to use an alternative effective fungicide which does not have a significant undesirable technological effect below a concentration of about 220 p.p.m. in natural rubber and to use this fungicide with the care required for an '8 p.p.m. fungicide' or a '25 p.p.m. fungicide'. The application of the general principle, that considerable care may be needed over the choice and utilization of fungicides for plantation crops, to the control of panel diseases of *Hevea brasiliensis* is also under examination.

I wish to thank the Administration of this Institute for permission to publish this communication.

Selection for an Invariant Character—'Vibrissa Number'—in the House Mouse

Waddington[1] has described selection experiments in *Drosophila* in which acquired characters were 'assimilated' by the genotype. This communication describes the initial results of a mouse experiment of similar design.

The character, 'vibrissa number', was scored by addition of the number of vibrissæ in the five minor groups found on the head and forelimbs of the mouse —a total of 19 'vibrissæ'[2]. Inbred lines *Aw*101 and *CBA* showed no variation in 'vibrissa number' and it was decided to use a parent stock based on these two lines in an attempt to break down the invariant vibrissa development. If this could be done it should be possible to breed mice with more or less than 19 vibrissæ.

Since it is possible for vibrissæ to fall out or be eaten, the best evidence of a real change must, at

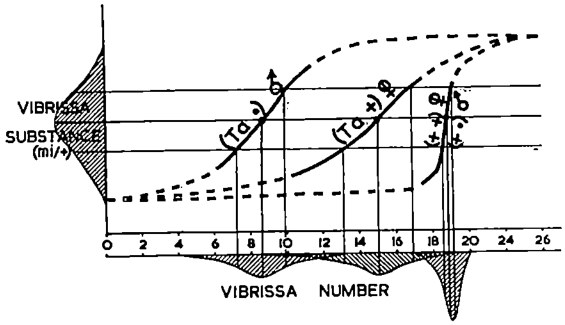

Fig. 1. Diagram illustrating the possible relationship between the genetic system determining the initiation of vibrissæ (*mi* − + genes); and the variation of vibrissa number in the (Ta − +) genotypes

least in the early stages, be looked for in the high selection line, that is, an increase of 'vibrissa number' is more convincing than a decrease. However, in an examination of 6,000 mice involving 14 strains, the post-orbital vibrissa was invariably present. Therefore, if there is loss of post-orbitals in the low line this can be taken as critical.

In order to produce phenotypic variance in 'vibrissa number', the sex-linked, semi-dominant gene Tabby (*Ta*) (Falconer, 1953) was crossed into the selection stock. Three frequency distributions are shown below the abscissa of Fig. 1. From right to left they refer to the 'vibrissa number' in (*a*) wild-type mice [(+ +) or (+ ·)], (*b*) (*T a* +) females and (*c*) (*Ta* ·) males. High and low lines were established by selecting within this uncovered variance.

Selection was applied both to (*Ta*+) females and (*Ta*·) males using consecutive matings of the form:

1. (+ +) female × (*Ta*·) male
2. (*Ta*+) female × (+ ·) male

The assumption was made that the same modifying genes influence both (*Ta*+) and (*Ta*·) scores. The changes in (*Ta*+) score support this as the two selection lines have been separated by three standard deviations in four generations.

Wild-type mice with low 'vibrissa number' became frequent in generations 5 and 6 of the low selection line and four of these mice had no post-orbital vibrissa. In generation 6, four mice with increased 'vibrissa number' appeared in the high line. Three of these mice had an extra supra-orbital vibrissa and one, 4 inter-ramal vibrissæ.

These results show, first, that there is genetic variation in vibrissa development which is not apparent in the absence of *Ta*. Using Waddington's terminology, vibrissa development is 'canalized'. Secondly, by selecting the variation which is apparent when *Ta* is present it has been possible to produce wild-type mice with both more and less than the standard number of vibrissæ. Although the genetic basis of these changes is unknown, it seems reasonable to suggest that the polygenic system controlling vibrissa development has been altered by selection.

It is possible to explain the absence of phenotypic variability in wild-type mice, despite the presence of genetic variability, by supposing a sigmoid relationship between the genetic actions and their phenotypic effects. If we assume a genetic system determining the form of this sigmoid relationship which is independent of the genetic system determining the initiation of vibrissæ, then it is possible to explain these results in terms of (*a*) the *Ta*/+ genes affecting the form of the sigmoid relationship and (*b*) a genetic system (*mi*/+) determining the initiation of vibrissæ. This is shown in Fig. 1, which demonstrates the parallel changes in 'vibrissa number' which occur when selection is applied within the Tabby genotype.

These results illustrate a function of major gene mutations in evolution, that is, to break down developmental homeostasis and so expose concealed genetic variation to natural selection.

Chromosome Variation in the *Heleocharis palustris-uniglumis* Complex

The *Heleocharis* (*Eleocharis*) *palustris-uniglumis* complex shows a considerable variation in chromosome number, the following figures being recorded in the literature: $2n = 10, 16, 32, 36, 38, 46$, *c.* 69, 92[1]. The taxonomical implications of this variation is under discussion[2–4], but no definite conclusions have been reached. It was felt that more information about the chromosome variation was needed before definite conclusions as to the taxonomical status of the different chromosome types could be drawn.

Counts of 158 specimens, mainly collected in Denmark and Sweden, gave the chromosome numbers indicated in Table 1.

Table 1. Chromosome Numbers of 158 *Heleocharis* Plants

$2n$	16	38	39	40	42	44	46	47	48	49	51
No. of plants	2	66	21	4	8	1	42	2	9	2	1

The taxonomical investigation of this material by Prof. Th. Sørensen is now in progress. Most of the plants with $2n = 38$ correspond to *H. palustris* (L.) R. et S., whereas the 46-chromosome type corresponds to *H. uniglumis* (Link) Schult. Plants with 38–46 chromosomes and those with more than 46 are more or less intermediate between *H. palustris* and *H. uniglumis*. They are all fertile, though some of them have a reduced fertility. It should be emphasized that the plants counted do not represent random samples from natural populations because intermediate types were deliberately selected for chromosome counting. These results suggest that '*H. palustris*' and '*H. uniglumis*' represent two semi-isolated entities. Hybridization takes place in Nature, and where *H. uniglumis* and *H. palustris* grow together the populations comprise both the two pure types with 38 and 46 chromosomes respectively, F_1 hybrids with 42 chromosomes and various back-cross or F_2, F_3 . . . karyotypes. Hence the *H. palustris–uniglumis* complex represents another case of introgression in the sense of E. Anderson[5]. The 16-chromosome type which is rare in Scandinavia but is the only type found in Greenland[4] and which is also common in southern Europe is probably completely isolated from the 38- and 46-chromosome types and should most likely be considered a separate species. It is undoubtedly split up in a number of subspecies[4]. The final decision as to the taxonomical status of the 38-chromosome '*palustris*'-type and the 46-chromosome '*uniglumis*'-type must await further morphological, cytological, and genetical investigations. The 10-chromosome type of Russian origin probably belongs to a different species. The plants of British origin with 92 and 69 chromosomes respectively which are referred to *H. uniglumis*[6] have not been found in Scandinavia. They may represent natural tetraploids and triploids respectively of this species or they may belong to a separate species. There is a conspicuous difference in chromosome morphology between *Heleocharis* and *Scirpus* species (which is one argument against merging the two genera into one). *Heleocharis* species have rather long chromosomes whereas *Scirpus* species have very tiny ones. Several *Scirpus* species have very high chromosome numbers (100 or more) and it would be interesting to know the chromosome morphology of the British 92-chromosome *H. uniglumis* type which was counted by Hartshorne (unpublished, ref. 1).

This work was supported by a grant from the Carlsberg Foundation.

Decision-making and the Communication of Information in an Industrial Setting

THIS communication is concerned with structural or organizational variables which may affect the transmission of information. It deals with a study which was made of variations in the communication patterns of four light engineering factories carrying out the same work. The communication structures in these factories were considered from the point of view of the individuals whose work required them to make decisions or estimates from production information available to them.

'Decision' in this context refers to daily operational judgments which are similar and recurrent, the effectiveness of which appears particularly dependent upon a knowledge of the outcome of previous judgments made earlier in the series. The particular decision discussed here concerns the estimate of delivery—the length of time which it is judged will be taken to complete a customer's order. Accurate delivery was especially important in the four firms studied since they were supplying components to customers who were also manufacturers with delivery dates to fulfil.

The way in which delivery time was estimated differed in the four factories. In *W* and *X* it was carried out by works estimators on the shop floor who were also responsible for maintaining their estimates. In *Y* and *Z* estimating was the function of office staff, physically isolated from the works. Fulfilment of the estimate was here the responsibility of works personnel, themselves isolated from the estimating process.

In order to assess whether variations existed in the ability of the four estimators to judge accurately, estimated and actual delivery times were compared in each of the four firms for all orders received during the same period of four weeks. In making the comparison error was measured in terms of the number of days by which fulfilment of an order exceeded or fell short of the estimated time. The range of error for each firm and a condensed distribution of items within this range are given in Table 1.

Table 1

	Estimates		Range of error	Percentage frequency of error (+ and −)				
	No.	Range		0–9 days	10–19 days	20–39 days	39+ days	
W	663	2–170	−214 to + 78	42	18	22	18	100
X	338	2–185	−197 to + 74	26	24	29	21	100
Y	540	3–205	−187 to +149	23	22	26	29	100
Z	461	3–256	−198 to +115	19	15	30	36	100

A more refined firm-by-firm comparison yielded the ranking *W*, *X*, *Y*, *Z* in order of accuracy of delivery estimating.

It is not sufficient to attribute this greater accuracy in *W* and *X* to the fact that estimators in these firms were responsible for their estimates and so 'allowed themselves longer', since their performance was superior whether the error taken into account was that of over- or under-estimation. A more reasonable explanation may be put forward in informational terms. Their position in the communication structure appeared to allow to estimators in *W* and *X* a direct, continuous and fairly immediate knowledge of the outcome of their estimates. Direct knowledge of results was available through their daily association with the manufacturing side of the business. In the case of *Y* and *Z*, any knowledge of results which existed appeared at best to be indirect, intermittent and retrospective.

This example illustrates one way in which the position of an estimator in a communication net may increase or reduce the likelihood of error in his estimates. It suggests that closer attention to structural variables and manipulation of the way in which a communication system is organized may help to reduce error commonly ascribed to unforseeable circumstances and uncontrollable factors.

The research to which this communication refers was sponsored by the Department of Scientific and Industrial Research and the Medical Research Council Joint Committee on Human Relations in Industry, and financed from Counterpart Funds derived from United States Economic Aid. A report has been submitted to the Committee. I am indebted to Mr. J. W. Whitfield under whose direction the work was carried out.

Feb. 4.

FORTHCOMING EVENTS

Wednesday, April 9

Oliver Bird Trust and the Society for the Study of Fertility (in the Lecture Hall, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5 p.m.—Dr. Gregory Pincus: "Fertility Control with Oral Medication" (Second Oliver Bird Lecture).

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2), at 5.30 p.m. —Informal Evening on "U.H.F. Test Transmissions".

Institution of Mechanical Engineers, Steam Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Combined Nuclear/Fossil Fuel Cycle".

Society of Chemical Industry, Food Group—Nutrition Panel (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Annual General Meeting, followed by the Fourth Meeting on "Some Nutritional and Allied Problems Confronting the Food Manufacturer". Dr. M. Ingram: "Technological Aspects of Chemical Preservatives"; Dr. J. M. Barnes: "Biochemical and Pharmacological Aspects of Chemical Preservatives".

Wednesday, April 9—Friday, April 11

Institute of Physics, Education Group (joint meeting with the UTH Western Branch, at the University, Bristol)—Conference "The Teaching of Science in Schools".

Thursday, April 10

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. A. Ratcliffe, O.B.E., F.R.S.: "Radio Observations on Artificial Satellites".

Société des Ingénieurs Civils de France, British Section (joint meeting with the Institute of Fuel, at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—M. André Blanchard: "Lacq: Its Problems and Potentialities".

Society of Chemical Industry, Microbiology Group (at Queen Elizabeth College, Campden Hill Road, London, W.8), at 6 p.m.—Annual General Meeting, followed by Dr. E. F. Gale, F.R.S.: "Nucleic Acids, What, Where, Why".

Royal Photographic Society (at 16 Princes Gate, London, S.W.7), at 7 p.m.—Mr. D. Causley: "Electronic Control in Photographic Printing".

Friday, April 11

British Psychological Society, Industrial Section (in the Department of Psychology, Birkbeck College, Malet Street, London, W.C.1), at 1 p.m.—Mr. Robert H. Guest: "Behavioural Effects of Managerial Change".

Institution of Electrical Engineers, London Graduate and Student Section (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. R. Carruthers: "The Engineering Aspects of the British Controlled Thermonuclear Reaction Experiments".

Saturday, April 12

South-Eastern Union of Scientific Societies (at the House of the Zoological Society of London, Regent's Park, London, N.W.1), at 10 a.m.—Conference on "Conservation of Nature in South-East England".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer in Inorganic Chemistry; and a Lecturer in Organic Chemistry—The Registrar, Hatfield Technical College, Hatfield, Herts (April 10).

Senior Lecturer (with a good honours degree or higher degree in chemistry and experience in industry, teaching and/or research) in Chemistry—The Principal, Wigan and District Mining and Technical College, Wigan (April 11).

Assistant Lecturer in Philosophy—The Registrar, The University, Leicester (April 12).

Lecturer (with an honours degree in botany with subsidiary qualifications in zoology, and teaching experience) in Botany—The Principal, Derby and District College of Technology, Normanton Road, Derby (April 12).

Principal (with high academic qualifications, and good teaching and industrial experience)—The Clerk to the Governors, North Staffordshire Technical College, P.O. Box No. 23, Town Hall, Hanley, Stoke-on-Trent (April 12).

Senior Lecturer in Mathematics—The Secretary, Royal College of Science and Technology, Glasgow (April 14).

Lecturer in Aesthetic Philosophy—The Secretary of University Court, The University, Glasgow (April 15).

Assistant Lecturer in Mathematical Statistics—The Registrar, The University, Manchester 13 (April 18).

Imperial Chemical Industries Research Fellows in Biochemistry, Chemistry, Engineering, Pharmacology or Physics —The Secretary, The University, Aberdeen (April 18).

Assistant Lecturer (with special interests or training in experimental and statistical psychology) in Psychology—The Registrar, The University, Manchester 13 (April 19).

Deputy Librarian (with a good honours degree and experience in a university or similar academic library, and preferably professional library qualifications)—The Secretary, University College, Gower Street, London, W.C.1 (April 19).

Lecturer (with a special interest in plant biochemistry. microbiology or associate fields) in Botany—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (April 25).

Assistant in Mathematics—The Secretary of University Court, The University, Glasgow (April 26).

Research Fellow in Mathematics—The Secretary of University Court, The University, Glasgow (April 26).

Assistant Lecturer (with a special interest in some aspect of vertebrate zoology) in Zoology—The Secretary and Registrar, University College of North Wales, Bangor, North Wales (April 30).

Forest Entomologist (with a postgraduate degree in entomology, and preferably experience in forest entomology) in the Department of Entomology, Waite Agricultural Research Institute (University of Adelaide)—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, April 30).

Junior Lecturer in Petrology; and a Junior Lecturer in Zoology—The Registrar, Trinity College, Dublin (April 30).

Lecturer (preferably with experience in electronics and instrumentation for automatic control) in Electrical Engineering—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (April 30).

Lecturers (preferably with a special interest in thermodynamics) in Mechanical Engineering—The Secretary of University Court, The University, Glasgow (April 30).

English Electric Research Fellow in Aeronautics, for postgraduate research into the problems of vibration or stability and control of aircraft—The Warden, The College of Aeronautics, Cranfield, Bletchley, Bucks (May 1).

Lecturer in Chemistry—The Secretary, Durham Colleges in the University of Durham, 38 North Bailey, Durham (May 1).

Reader in Mechanical Engineering at the Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (May 1).

Reader in the History of Philosophy at the London School of Economics and Political Science—The Academic Registrar, University of London, Senate House, London, W.C.1 (May 2).

Assistant Keeper in the Department of Geology—The Secretary, National Museum of Wales, Cardiff (May 14).

Assistant Lecturer (Demonstrator) in Anatomy, to undertake teaching and research—The Secretary, University College, Gower Street, London, W.C.1 (May 15).

Computer (preferably woman graduate) in the Mathematics Department—The Assistant Secretary, University College, Gower Street, London, W.C.1.

Electrical or Mechanical Engineer in the Department of Physics, to form part of a research team developing a linear accelerator for nuclear physics research—Prof. S. Devons, The University, Oxford Road, Manchester 13.

Fisheries Research Officer (with an honours degree in biology with emphasis on zoology; appropriate knowledge of chemistry and of statistical methods; and the ability to read French and possibly German) with the Federation of Nigeria, to undertake research into pond culture of local species of fish and into the chemistry and plankton populations of fish ponds to ensure the most profitable use of available nutrients, foodstuffs and fertilizers—The Director of Recruitment, Colonial Office, London, S.W.1, quoting Ref. BCD.65/14/01.

Head (graduate with good industrial and teaching experience) of the Department of Mechanical Engineering (Grade III)—The Principal, City of Bath Technical College, Lower Borough Walls, Bath.

Head of the Feeding and Metabolism Department—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 58/8.

Lecturer in Geography, and a Lecturer in Mathematics—The Warden, Goldsmiths' College (University of London), New Cross, London, S.E.14.

Lecturer or Assistant Lecturer in Inorganic Chemistry—Prof. G. Wilkinson, Imperial College, London, S.W.7.

Lecturer (preferably with teaching experience and a special interest in biochemistry) in Physiology—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8.

Lecturer (with a suitable degree and industrial research experience) in Metallurgy—The Deputy Registrar, The University, Birmingham 15.

Lecturer (with some industrial research experience, and preferably teaching experience) in Physics—The Principal, Royal Technical College, Salford 5.

Lecturers and Assistant Lecturers in Electrical Instruments, Telecommunications, Applied Electronics and General Electrical Engineering—The Secretary, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

Master (well qualified) to teach Chemistry—The Headmaster, School House, Berkhamsted, Herts.

Physicist (Scientific or Experimental Officer grade), to develop heavy particle detectors and undertake fundamental research as a member of a team studying charged particle reactions using a 50-MeV. proton linear accelerator—The Recruitment Officer (1047Y/34), Atomic Energy Research Establishment, Harwell, Didcot, Berks.

Plant Pathologists (with some postgraduate experience), to investigate diseases of cotton in Africa—The Secretary, Empire Cotton-Growing Corporation, 12 Chantrey House, Eccleston Street, London, S.W.1.

Senior Pathological Technician (male or female)—The Secretary, Wembley Hospital, Wembley, Middlesex.

The Faraday Society

A GENERAL DISCUSSION
on
IONS OF THE TRANSITION ELEMENTS

will be held in Dublin from the 9–11th September, 1958, at the joint invitation of Trinity College (University of Dublin) and University College (National University of Ireland).

The Discussion will be divided into two main sections:

I. Optical and Magnetic Properties.
II. Energetics of Complexes.

It is proposed to exclude rare earth and transuranium elements and to concentrate on those aspects where the physical and chemical aspects of the subject come together.

Anyone wishing to contribute a paper should write to the Secretary, enclosing a brief summary, as soon as possible.

The Faraday Society, 6 Gray's Inn Square,
London, W.C.1.

GREEN'S

PURE FILTER PAPERS

HAVE BEEN USED BY MANY FAMOUS CHEMISTS FOR 40 YEARS.

Write today for a copy of "N Signposts", an interesting 20-page guide book on the use of filter papers

J. BARCHAM GREEN LTD.
MAIDSTONE, ENGLAND

2-micron stage micrometer

We proudly announce that our S.12 Stage Micrometer is now in production. This divides 100 microns into 50 parts of 2 microns each, numbered every tenth line.

We have taken great pains to ensure the highest accuracy for this new scale which should be invaluable for calibrating with top power objectives.

Price 90/- each.

Fully illustrated catalogue sent free on request.

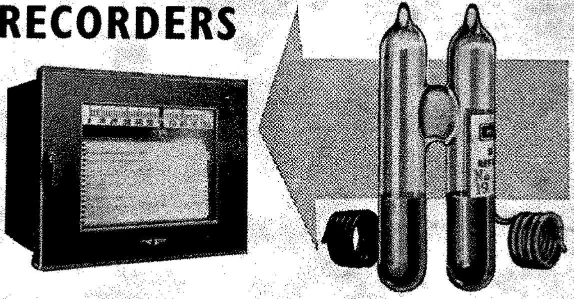
MUIRHEAD D-845 CELLS FOR RECORDERS



These cells will function under widely varying temperature conditions—be tolerant to a wide range of mounting positions — withstand rough handling and yet maintain an accurate and stable reference voltage. Mounted and unmounted types are available from stock.

E.M.F. 1·0193 volts absolute, subject to manufacturing tolerance of 0·0005 V Unmounted, 0·0002 V Mounted.
Temperature coefficient Does not exceed 5μV/°C over the range 10°—40° C.
Temperature hysteresis Negligible over the normal temperature range.
Internal resistance at 25° C. Average 800 ohms, maximum 1200 ohms.

SHADOW-CASTING

A NEW EVAPORATION UNIT TO MEET THE HIGH MAGNIFICATION STANDARDS OF MODERN ELECTRON-MICROSCOPES . . .

Shadow-casting is the answer to high resolution work, but the very high magnification standards of modern microscopes demand extremely accurate evaporation without defects.
The "SPEEDIVAC" 12E6 is specially designed to meet these requirements.

MODEL 12E6 VACUUM COATING AND SHADOW-CASTING UNIT

- ★ Fitted carbon evaporation source for carbon replica work.
- ★ Special workholder allows specimen to be accurately adjusted for height from, and inclination to, the baseplate.
- ★ A 4 in. vapour pump for fast pumping.
- ★ Ballast tank for vibration-free running.

For better vacμμm service . . .

EDWARDS HIGH VACUUM LTD

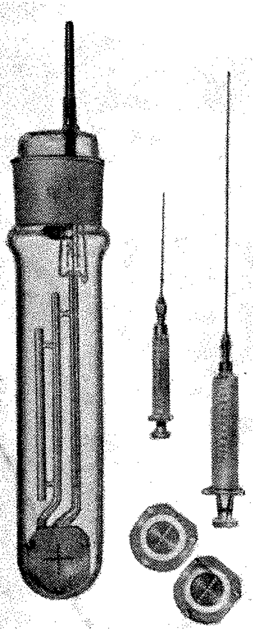
The **P.C.L. Pinner-Stabin Osmometer**

J. Polymer Sci. **9**, 1952, 575



For the measurement of molecular weights of polymers, proteins, etc., by the osmotic method.

Combines large membrane area and small volume, hence rapid attainment of equilibrium.

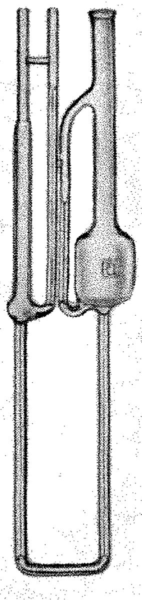
Designed for use at elevated temperatures.

Can be filled and emptied repeatedly without removal from thermostat.

All parts interchangeable.

★*Two examples of our service to the science of macromolecules.*

The **P.C.L. Zero-Shear Viscometer**



For investigating flow characteristics of fluids at very low rates of shear (c. 1 reciprocal second).

Can also be used as a normal dilution viscometer.

Specially designed for ease of cleaning.

Our Standard P.C.L. Suspended-Level Dilution Viscometer also available.

★*Further details of the above and of our other " Services to Polymer Science " gladly sent on request.*

CULCHETH and HARROW

Laboratory research, by its nature, is always ahead of site construction. At the Research and Development Laboratories of the United Kingdom Atomic Energy Authority at Culcheth, for example, the scientists and technicians are today testing and specifying materials for nuclear power projects which have not yet come off the drawing boards.

At the service of U.K.A.E.A. scientists — and of all engaged in nuclear engineering — are the facilities of the Kodak Laboratories at Harrow. Here more than 200 qualified scientists, with specialists on every side of photographic and radiographic inspection, are constantly at work serving their fellow scientists and engineers.

If there is any aspect of scientific photography or radiography on which you would like advice and information, please write to

Kodak LIMITED
INDUSTRIAL SALES DIVISION
Kodak House, Kingsway, London, W.C.2

THE CHIEF APPLICATION of photography at the U.K.A.E.A. laboratories at Culcheth is in recording details of apparatus, specimens, and metallurgical structures for later use in technical reports.

Photomicrography is employed extensively, the main uses being in studies of the grain size and structure of proposed canning materials and of possible uranium-based fuels before and after mechanical tests and in various conditions of heat treatment. Photomicrography is also used in studies of modes of deformation of uranium. Optical and electron micrograph investigations are made of structural changes in potential pressure vessel steels.

Time-lapse cinematography is used to record the sequence of dimensional changes during the thermal cycling of uranium.

Photographic methods are used to record diffracted x-radiation during the study of crystal structures.

DIRECT READING pH METER

MODEL 23A

This high-grade laboratory pH Meter is one of the most widely used instruments in electrochemical research.

Some 50 different types of electrodes are available for pH, redox and micro analytical work. Stable to 0.02 pH with a B.S. precision grade meter and a recorder output.

INDUSTRIAL HEALTH PROBLEMS IN THE USE OF NUCLEAR ENERGY

THE second of the Committees of Inquiry set up under the chairmanship of Sir Alexander Fleck following the accident to Windscale Pile No. 1 on October 10, 1957, was "to review the organization within the Atomic Energy Authority as a whole for control of health and safety and to make recommendations"; a survey of the report appears on p. 1043 of this issue. The Committee appointed to examine the organization and staffing of parts of the Authority has already reported and attributed the accident primarily to an insufficiency of senior technical staff in the Operations Branch. The strengthening of this Branch was regarded as a first essential even if it involved some curtailment of developments elsewhere. Understaffing is also the primary trouble revealed by the examination of the Authority's organization for control of health and safety*. The Committee is satisfied there are no fundamental weaknesses, but is concerned to note that the acute shortage of expert health and safety staff means that the planned organization is seriously under strength in the higher posts. The health and safety organization is called upon to perform a wide variety of duties, both internally and externally, many of which require expert qualifications in more than one of the fields of medicine, radiology, health, physics, mathematics, nuclear physics or nuclear engineering. The review revealed an acute shortage of people possessing the requisite qualifications; throughout the Authority there were only about ninety people possessing honours degrees or equivalent qualifications who were engaged full-time on the control of health and safety.

Nor is it simply that these people are seriously over-burdened, with the result that the safety officers at Windscale had had little exact guidance about the amount of radioactivity that could safely be allowed to accumulate in the area. With the development of the nuclear power programme and the increasing use of radioactive materials in medicine, agriculture and many parts of industry, the demand for specialist health and safety staff will increase still further. That much is attested by the annual report† of the Chief Inspector of Factories for 1956 (see p. 1043 of this issue), which followed that of the Fleck Committee. Not only is the question of safety in nuclear power stations one of the four main topics which Sir George Barnett selects for discussion in this, his last, report, but also elsewhere in the report the use of ionizing radiations in industry is discussed at some length. What the Fleck Committee urges as to the desirability of making the field of health and safety provide an attractive career for those able to acquire the necessary expert knowledge, finds ample corroboration in Sir George Barnett's report.

For the Authority this would involve, the Committee points out, permitting greater flexibility in salaries, particularly for the specialist medical staff needed to head the integrated health and safety organizations in the works of the Industrial Group. More important still, the Fleck Committee considers that the Authority, as the vanguard of the nation's effort in nuclear energy, should assume responsibility for building up the supply of expert health and safety officers at all levels, from managers to the technicians who will be required in ever-increasing numbers by the electricity authorities and industry as well as by the Authority itself. The main instruction in the United Kingdom on the health and safety problems of nuclear energy has hitherto been given by the Authority as part of its courses in the Reactor and Isotope Schools at Harwell and the Reactor Operations School attached to Calder Hall. Factory inspectors are now taking short courses at Harwell to help them in inspecting industrial establishments where radioisotopes are in use.

This has covered only a small part of the field, and the Fleck Committee holds that more comprehensive instruction is needed. In view of the urgent need and the impact of the shortage on the Authority, the Committee recommends that the Authority should take the lead in this matter, by establishing a national training centre for health physics and nuclear safety staff (under the administration and general supervision of its Research Group) where courses should be graduated to suit all levels and cover not only problems of protection against radiation hazards, but also the health and safety aspects of the use of isotopes in medicine, agriculture and industry. In the medical field, the Authority should be prepared to recruit and to finance the specialized training of candidates who will be required for future management posts, and the Committee visualizes this specialized training as being worthy of recognition as a new professional qualification. Moreover, the Authority should also recruit and give training on the job to the medical staff required to provide the new type of medical service, as well as recruit and train a cadre of health physicists and nuclear safety experts commensurate with the future needs of the nation as a whole. It is recommended that Government departments should be directed to ensure that appropriate training in radiological problems is given to the public services and industries for which they are responsible

The Committee's specific recommendations regarding the Authority's internal responsibilities and organization are summarized elsewhere (see p. 1043 of this issue); but before considering the implications of the assumption by the Authority of such national responsibilities for leadership, the background against which these recommendations are made must be appreciated. The Committee was particularly conscious that the accident at Windscale brought to the surface the latent public anxiety about the hazards of nuclear energy. Now that the nation is committed to a large nuclear-power programme, the Committee holds, and rightly, that it is of the first importance that the hazards of nuclear energy should neither be exaggerated nor minimized in the public mind. The Authority has sought to err on the side of caution and, within the limits of existing knowledge, takes no chances. The Health and Safety Organization plays a major part in the Authority's affairs, and the Committee is satisfied that in general the Authority's policy has hitherto been governed by the considerations that operating procedures and codes of practice must not risk endangering workers or the public and, within the limits of human ingenuity, must be proof against human failure.

---

* Atomic Energy Office. Report of the Committee appointed by the Prime Minister to examine the Organisation for Control of Health and Safety in the United Kingdom Atomic Energy Authority. Pp. 28. (Cmnd. 342.) (London: H.M. Stationery Office, 1958.) 1s. 3d. net.

† Ministry of Labour and National Service. Annual Report of the Chief Inspector of Factories for the year 1956. Pp. 195. (Cmnd. 329.) (London: H.M. Stationery Office, 1958.) 9s. 6d. net.

Nevertheless, the Committee became aware that besides making good the deficiencies in the Authority's organization, there is urgent need to clarify the relations between the many Government departments concerned with health and safety in the field of nuclear energy and to strengthen the co-ordination between them. That is the reason for the recommendation that the Atomic Energy Authority should be built up to enable it to play the leading part and ensure that all necessary action is initiated in good time. Since the ultimate responsibility for assuring safety in relation to nuclear energy must be borne by the Government, it is of vital importance, the Committee urges, that this major improvement in organization should be made. Linked with it, of course, is the question of public confidence, and while the Committee endorses the arrangements for local liaison which the Authority has initiated, it recognizes that special care is required in public relations; and it therefore recommends that the Authority should review present procedures for publishing information about accidents, with the view of giving a prompt account of such occurrences in as much detail as may be appropriate. Moreover, apart from its bearing on health and safety, public confidence could be a decisive factor in the smooth implementation of the nuclear power programme.

The three most important implications of these recommendations are in respect of staff, of finance and of time, and all three are appropriately considered in the context of Sir George Barnett's valedictory report as chief inspector of factories. It will be recalled that even before the publication in October 1956 of the report on the staffing and organization of the factory inspectorate, the Minister of Labour had announced his decision to treble the size of the Engineering and Chemical Branch of the inspectorate, and to increase that of the general inspectorate by 26 posts. Nevertheless, at the end of 1956 Sir George Barnett reports that only 375 out of an authorized 439 posts were filled, and 25 inspectors were lost during the year, 17 by resignation. On February 5 the Minister of Labour, Mr. Iain MacLeod, said there were still 33 vacancies, though the number of inspectors had risen to 394 with 15 awaiting appointment, and there had been only 9 resignations in 1957. The present recruitment situation in the general inspectorate was not unsatisfactory, and it was hoped to fill the three vacancies in the Medical Branch from an open competition.

This position, as the White Paper on the Factory Inspectorate fully recognized, is related to the national shortage of scientists and technologists. Of this the Fleck Committee was no less cognisant; but none the less its argument that an adequate proportion of that scarce and limited man-power must be directed to this field, even at the cost of curtailment elsewhere, cannot be gainsaid. Moreover, in stressing the need for making the conditions and opportunities of service more attractive, it is again in harmony with the findings of the White Paper, and these steps could well further that greater esteem and understanding of the factory inspectorate's work which is so important for efficiency and recruitment. Taking a long view, that report was concerned not to advance unreasonable claims for expanding or even maintaining the factory inspectorate. On the contrary, it conceded the possibility, and even the probability, that with continuing improvements in the design and operation of factories and industrial processes, the cumulative effect of the work of the inspectorate would permit a substantial reduction in the resources of man-power devoted to factory inspection.

That almost certainly is the way in which the most efficient use of highly trained man-power is to be achieved and if, by emphasizing the opportunities for scientific work which careers in industrial health and safety offer, and ensuring that the conditions of service are appropriate, we can attract sufficient recruits of high ability, the purpose of industrial health and safety should itself be more effectively served than by reliance mainly or solely upon the inspectorate. For many years to come, the need for close co-operation will remain and there will be much, possibly even more than to-day, for the inspectorate to do; but it is in harmony with the whole trend of the Chief Inspector's report that such work should be done primarily and to the maximum degree from within industry.

That is only part of the picture. The Fleck Committee was not solely concerned with the supply of specialists of high qualifications and ability; it recognized the need for expert health and safety staff at all levels—from managers to technicians. There is a significant section in the chapter on accident prevention in Sir George Barnett's report which bears on this. In many sections of the Factories Acts and in some codes of special regulations made under the Acts, an employer is required to have certain duties carried out by a "competent person" or a "responsible person". These duties are very varied and include, among others, the detailed technical inspection, examination or testing of boilers and autoclaves, lifting machines and appliances, scaffolds, breathing apparatus and ventilating plant. This work plays a most important part in ensuring the safety and health of workers, but in general receives little public notice unless something goes wrong.

There are two points to be emphasized here. First, the adequacy and effectiveness of such work go far to determine both the effectiveness of the control exercised by the more highly qualified health and safety officers, and also the number of such officers required. In other words, it determines the most efficient and economical use of the most highly trained categories of scientists and technologists. Secondly, those carrying out such duties are themselves essentially specialists. Indeed, at one extreme they may require to be scientists or technologists possessing fundamental theoretical knowledge combined with sound practical experience of the kind of plant to be examined; and while other work may require less technical knowledge, good experience and sound judgment are invariably required.

We are thus once again touching an important facet of the problem of technical education, and it is obvious that if the full benefit of the recommendations of the Fleck Committee in the comparatively limited field of nuclear energy are to be realized, due attention must be given to the extension and improvement of technical education, as the Chief Inspector himself notes in a specific reference to the technical colleges. Where that reaches a sufficient standard, it is clear from the Chief Inspector's current report there is little cause of complaint, for example, in chemical works. Nevertheless, as the report insists, the work of the "competent person", however high his qualifications, must be integrated with that of the accident prevention organization as a whole; and meticulous care and close and harmonious relations between the different works departments concerned, the safety organization and the inspectorate are essential.

That, of course, means finance as well as manpower, and it is important to emphasize, at a time when the Government is pre-occupied with economy, that industrial health and safety involve expenditure. But wise investment in this way brings a return many times over in industrial efficiency, altogether apart from the elimination of human suffering and loss of life. A programme such as the Fleck Committee has outlined will involve the expenditure of considerable sums, which will have to be found, even at the cost of curtailing expenditure elsewhere.

Thirdly, there is the question of timing. The Fleck Committee rightly insists that action is urgently needed and cannot wisely or safely be postponed. The health and safety specialists, the safety organization and codes and the supporting technicians must be trained in advance, so that they are ready to take up their duties as soon as they are needed. Preparation cannot be deferred just because the new power stations are only being planned or under construction, still less because a time of national economy is inconvenient for incurring such expansion in expenditure. There could be no plainer warning to both major political parties to seek to agree on what sacrifices in non-essentials—even in the social services—it may be necessary to recommend to the country, to ensure that the health and safety of the workers concerned and of the nation as a whole are fully secured.

EVOLUTION AND ORGANIZATION

The Strategy of the Genes

A Discussion of Some Aspects of Theoretical Biology. By Prof. C. H. Waddington. With an Appendix by Dr. H. Kacser. Pp. ix+262. (London: George Allen and Unwin, Ltd., 1957.) 28*s.* net.

AMONG the more important of the advances that are at last really bringing us to grips with the relation between genetics and evolution is Waddington's experimental demonstration of the genetic assimilation of acquired characters, an apparently 'Lamarckian' phenomenon that needs no 'Lamarckian' explanation. In this book Waddington discusses the concepts that led to and arise from such experiments and considers some of their consequences. There is also a discussion by Kacser of models based on chemical kinetics that have relevant properties.

The most essential concept is that the processes of development are canalized so that the effects of disturbances are not random, but tend to be buffered or damped or otherwise compensated for by consequential effects that leave the resulting organisms 'organized'. From this basis, through a discussion of "the cybernetics of development" Waddington develops his model, the "epigenetic landscape", which pictures the probabilities that development will follow particular paths to given end-results. The contours of the landscape are determined by the genotype, and the process of development is represented by a ball rolling down the valleys.

This model provides a picture of the organization of developmental processes that aids discussion of the different properties of epigenetic systems and classification of selection "in relation to the type of effect which it produces". Canalized development may involve narrow valleys, or broad U-shaped valleys that permit minor modification by environmental or genetic variation. It may be flexible, alternative valleys being available into which the ball may be pushed, perhaps over a threshold, by environmental switches, and which lead the organism to different adapted forms; and it may be "noisy" in the sense that random sources of variation are inadequately buffered (represented by imperfections of the ball's surface). Selection in consequence may be not only progressive or directional, but also it may be stabilizing if it increases the canalization of the valleys (as opposed to normalizing if it reduces the variety of genotypes), and it may operate against "noise" so that homologous organs come to differ less. It may also be "disruptive" (Mather), though Waddington thinks, surely erroneously, that "this can be adequately regarded as a sub-type of the more usual unidirectional selection".

Such a model of developmental organization helps greatly the understanding of the effects we may expect different modes of selection to have. It is especially helpful in illustrating the way in which an environmental switch that pushes development over a threshold into an alternative path may aid selection of those genotypes which make the threshold lowest. Selection may thus produce a population in which the new path may be canalized by further selection until it becomes the norm even in the absence of the environmental switch. Waddington's discussions of these topics should interest all and stimulate many biologists.

But the model has its limitations. Waddington is aware of this; but nevertheless seems to push it too far in some respects. The model to some extent divorces genotype from environment and genes from other genes in a new way. Thus the landscape (Fig. 5) has its form determined by genotype, and an acquired character results if an environmental factor pushes the ball over a threshold into a valley not normally followed. "Organic selection" can then (Fig. 30) select a mutant allele that replaces the environmental switch, or "genetic assimilation" can change the landscape so that the threshold is removed. This seems to involve a distinction between landscape genes, ball-pushing genes and ball-smoothness genes (responsible for reducing developmental noise), though they are all landscape genes by definition. Thus noise genes "probably play relatively little part in evolution", though it seems impossible to see any difference in principle between them and canalizing genes which do.

It seems to be this tendency to push the model too far that leads Waddington to wonder speculatively at the origin of the ball-pushing mutants in his experiments, and he tentatively speculates whether the biochemical situation responsible for the landscape and altered by the environmental switch may not itself be responsible for the mutations. Here Waddington comes full circle and wonders whether the 'Lamarckian' phenomenon that he has demonstrated to need no 'Lamarckian' explanation does not need a 'Lamarckian' explanation after all. Now we must agree that mutation is often termed random very loosely, and that the class of viable mutations is clearly restricted to those to which the rest of the genotype is preadapted in the environment(s) in which the organisms must survive; and we must also keep an open mind concerning the possibility of genuine directed mutation. But it seems inappropriate to speculate whether directed mutation may be involved in particular experiments without first eliminating other more plausible hypotheses. Even if it were necessary to suppose that the mutant genes in Waddington's experimental populations have been produced by his experimental conditions, there is more than one plausible mechanism that does not involve directed mutation. In particular there is evidence that the stability of meiosis is easily disturbed, and therefore it is possible that selection may change the frequency and spectrum of recombination and thus increase the likelihood that particular recombinations with relevant effects may arise. Waddington admits that rare recombination and mutation may be hard to distinguish, but does not seem to see that this does not make the distinction any the less important.

This leads to the major criticism that must be made of this book. Throughout, the part played by linkage in maintaining the organization of development is belittled or ignored (as a consequence of which scant recognition is given to Mather's work). But in the face of evidence that genes of major effect are themselves linked complexes and that recombination can of itself give lethal effects, especially when the recombining chromosomes come from unrelated populations, it is impossible to believe that the organization of development does not involve the organization of genetic material into linked groups. To Waddington, the role of linkage is to be viewed in terms of the tactics of the genes; their strategy involves their part in the organization of development. But this is because he clearly regards the egg as the hen's means of making another hen, for he is discussing (preface) "biological organization and the developmental processes that *bring it into being*" (my italics). But "the hen is the egg's means of making another egg" is a re-statement of the same truth. More attention to the biological organization at the *beginning* of the developmental time-scale would improve this illuminating and stimulating discussion of the organized developmental processes that Waddington calls the epigenetic system. THE WEALTH OF INDIA

The Wealth of India

A Dictionary of Indian Raw Materials and Industrial Products. Raw Materials, Vol. 4: F–G (with Index). Pp. xxviii+287+13 plates+viii. (New Delhi: Council of Scientific and Industrial Research, 1956.) n.p.

The fourth volume of "The Wealth of India" closely resembles its predecessors, that is to say, it is a scholarly production overflowing with up-to-date information. Unfortunately, much to the regret of the compilers, circumstances over which they have no control have resulted in an interval of nearly four years between the dates of issue of Vol. 3 and 4, and even now it has not been possible to include the obviously important article on "Fish and Fisheries". It is pleasing to note that those responsible are taking all possible steps to expedite the completion of the series.

It is difficult to compile information; it is still more difficult to decide what to leave out in order to satisfy the average reader who requires his information to be as concise as possible, especially when economic subjects are in question. The advisory board for the present publication realized this fully, and in 1943, before work was started, drew up a number of admirable directions for the editorial board. It is regrettable to find that many of these have now been ignored. The maximum length of a major contribution was not to exceed twenty-five pages of the book as now printed, and yet "Gossypium" covers eighty-two. This article, with its three beautiful coloured plates, 44 figures and 64 tables, occupies nearly one-third of the whole volume, and although difficult to compress, contains much which could be omitted with advantage. Photographs of 158 cotton samples distributed through 63 pages so that comparison is hindered seem unduly numerous; the table showing the properties of these fibres is much more informative. On the other hand, two excellent maps indicate so clearly the acreage and production of cotton and the spread of improved types that the corresponding tables appear unnecessary. Many of the tables are of interest only to specialists who might prefer to consult the original sources, reference to which is invariably given. Much space is taken up by detailed statistics for each main political division of India. This seems inappropriate in view of the almost complete absence of correlation between cotton growing and State boundaries. One table gives a number of analyses of black cotton soils differing widely in composition, but no indication of their value for growing cotton. The large amount of matter of secondary importance tends to obscure much that is interesting and informative, and it is suggested that in future all major articles should be preceded by a table of contents.

There is some tendency to give over-elaborate descriptions of products not well established in India although common in other countries. For example, the comprehensive article on soybean, admirably written, seems far more detailed than is required to show the importance of this commodity and the desirability of extending its cultivation in India. Many of the analyses given refer to material of foreign or unknown origin and are of little value, whereas comparative figures for Indian and foreign products, such as those given for fennel and tallow, often reveal striking and important differences. Production figures for cotton in tons, bales, maunds and candies do not conduce to clarity. Lastly, a few of the illustrations are of poor quality in marked contrast to the majority, and do nothing to elucidate the text.

The above remarks are not intended to disparage, but to convey a few impressions of an important and valuable book. To increase its value still more it is hoped that the practice of issuing provisional subject indexes will be continued and that they will be in even greater detail than that attached to Vol. 3.

H. E. WATSON

EAST AFRICAN MOUNTAIN FLORA

Afroalpine Vascular Plants

A Taxonomic Revision. By Olov Hedberg. (*Symbolae Botanicae Upsalienses* 15 : 1.) Pp. 411+12 plates. (Uppsala : A.-B. Lundequistska Bokhandeln, 1957.) 40 Kr.

SINCE the extraordinary vegetation of the African equatorial mountains was revealed during the latter part of last century, the problems of its relationships and the reasons for its occurrence have exercised the minds of botanists. In this region, where the chill of a rarified atmosphere tempers the heat of a tropical sun, and where there is little variation throughout the year in the length of day and night and in the range of temperature, the flora is of exceptional interest. Nowhere in the world are alpine landscapes so weirdly beautiful as on these mountains of East Africa. Each mountain group in its higher zones has an assemblage of species the nearest relatives of which do not occur at lower altitudes on the same mountain, but in the corresponding zones of neighbouring though totally isolated mountains. In the alpine regions there is some degree of endemism, but it is the vicarious species of genera such as *Lobelia*, *Senecio*, *Helichrysum* and *Alchemilla* that pose interesting problems in regard to common ancestry and comparatively rapid rates of evolutionary diversification on the various mountains. On the other hand, there are species which are common to some of these mountains and the north temperate region the isolation of which has not produced any significant morphological change.

The first attempt to consolidate and summarize knowledge on the flora of the tropical African mountains was Engler's work "Über die Hochgebirgsflora des tropischen Afrikas", which was published in 1892. Engler's material was very sparse and almost entirely confined to collections made on Kilimanjaro, the other mountain groups at that time being virtually unexplored botanically. In the present century there have been a number of well-organized expeditions to all the high mountains of East Africa and splendid collections have accumulated, especially at the British Museum, Kew and botanical institutions in Sweden. There was urgent need for a thorough taxonomic study of this unique dispersed flora and Dr. Hedberg's revision is a massive and authoritative *exposé* of the subject. His survey is rather arbitrarily confined to the species which occur in the alpine belt immediately above the heath forest. This has the merit of giving some definite topographical and ecological limits to the work and bringing the treatment of the material within manageable scope, though, with the exclusion of the ericaceous belt, and also the bamboo zone and the mountain forest, many of the most interesting elements in the flora are eliminated. The closeness of the links between the mountains is thus more obscure and the interesting intra-continental relationships with floras of West Africa, the Cape and the Mediterranean basin are unrecorded.

In his taxonomic analysis Dr. Hedberg has taken a tolerant and sensible view of the various taxa, particularly in his conclusions on the species which have a wide distribution in the north temperate zone. He has laid stress on resemblances rather than on differences and has thus resisted the modern tendency to recognize critical units.

The work is well produced with a judicious number of text figures and a supplement of habitat photographs of certain species. Altogether this account of the Afroalpine vegetation is one of the most significant and meritorious recent contributions to the study of the African flora.

G. TAYLOR

ECONOMIC THEORY

The Theory of General Static Equilibrium

By Prof. Eraldo Fossati. Edited by Prof. G. L. S. Shackle. Pp. xvi+247. (Oxford : Basil Blackwell, 1957.) 30*s.* net.

THE lectures on economics which Prof. E. Fossati gave when he was at the University of Trieste have been known at second hand by many economists in Britain, and by the few proficient in Italian in more detail through his "Elementi di economia razionale", first published in 1946. The volume now reviewed is an English version of the fourth edition (1954) of Prof. Fossati's text. It is not simply a translation, but rather a new edition by an outstanding English theoretical economist. Prof. G. L. S. Shackle explains in his foreword that he found the text in need of "re-expression in the forms of thought with which the English-speaking economist works". Consequently "this English version has been entirely written out in my own hand in phrases which are mostly of my own choosing".

The student of economic principles in Britain, brought up in the Marshallian tradition, tends to acquire a knack for improvization, to assume away the less immediately relevant interdependencies in his problem and to concentrate on those analyses which involve the view of the problem through time. He usually lacks the guidance which can be provided by Pareto's unifying concept of general static equilibrium. As Prof. Shackle points out, it is not generally possible to get him to read Pareto's "Manuel". The present version of a text by a brilliant successor and expositor of Pareto should redress the balance. It will certainly be welcomed by all teachers of courses in general economic principles and it should make a most valuable, if subsidiary, text to put in the hands of students.

The scope of the book is not quite as limited as the title might indicate. One of Prof. Fossati's contentions is that the theory of general static equilibrium is not only of importance in itself but also serves as "a powerful apparatus for dynamic analysis . . . by offering deep insight into the reaction of representative consumers and entrepreneurs to given situations . . . and through the process of model construction, it paves the way to econometric research" (author's preface, p. xii). There are chapters towards the end of the book, simple and even sketchy though they may be, which introduce the student to stability conditions, to money, risk and uncertainty, and to the stochastic approach in econometrics.

On the other hand, though Prof. Fossati has written with recent developments in economic theory in mind, the text remains a version of the scheme originally elaborated more than ten years ago. It cannot be expected, therefore, that the analysis is completely up to date, still less that it should emphasize those particular lines of thought most familiar to Anglo-American economists. Indeed, Keynes gets no more than one incidental mention and Leontief none at all; nor is the 'linear programming' school represented. In fact, following Pareto, the treatment is strictly confined to continuous analysis of the familiar marginal type, easily expressible in terms of the calculus.

The mathematics, it should be noted, are largely relegated to appendixes to the various chapters. The exposition is designed to be simple, clear and lucid, and it succeeds admirably. There are adequate lists of books and articles to assist the student in his further reading. R. G. D. Allen

LIPID BIOCHEMISTRY

The Lipids

Their Chemistry and Biochemistry. By Prof. Harry J. Deuel, Jr. Vol. 3: Biochemistry—Biosynthesis, Oxidation, Metabolism, and Nutritional Value. Pp. xxxvi+1065. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 25 dollars.

The late Prof. H. J. Deuel set himself to write a single treatise on the chemistry and biochemistry of lipids and with the appearance of this third volume his monumental task is complete. Volume 1 describes the chemistry of the lipids (*Nature*, **170**, 727; 1952) and Volume 2 deals with some aspects of their biochemistry: digestion, absorption, transport, and storage (*Nature*, **177**, 1050; 1956). The present volume covers other aspects of lipid biochemistry, in particular biosynthesis, oxidation, metabolism, and nutritional value.

After a brief introductory chapter, three chapters (266 pp.) are given to an account of the biosynthesis, oxidation, and metabolism of fatty acids, glycerol, and the triglycerides. Then come chapters on the oxidation and metabolism of phospholipids and their hydrolysis products (18 pp.), on the role of formic, acetic, and propionic acids in fat metabolism (38 pp.), and on the metabolism of branched-chain acids, hydroxy- and keto-acids, di- and tri-basic acids, acid amides, aldehydes, and hydrocarbons (70 pp.). There follows an account of the metabolism of cholesterol and related sterols (60 pp.), the carotenoids and vitamins A (200 pp.), vitamins D (62 pp.), vitamins E (68 pp.) and vitamins K (32 pp.), and the final chapters are devoted to the essential fatty acids (52 pp.) and the nutritional value of fats (99 pp.). The book has three indexes covering 130 pp. Each topic is covered in the same comprehensive and impartial manner which the author has displayed in earlier volumes. More than five thousand references are listed including several to publications in 1956, and only very few trivial errors have been noted in the text.

Prof. Deuel had prepared the text of this volume before his death in 1956, so that, although his colleagues and friends assisted in the later stages of publication, the book remains his. With its companion volumes it will long be a standard work in this field and a tribute to H. J. Deuel's zeal, industry, and enthusiasm. The text is prefaced by a biographical note about the author written by George R. Cowgill. F. D. Gunstone

ENGINEERING THERMODYNAMICS

Engineering Thermodynamics

Work and Heat Transfer. By G. F. C. Rogers and Y. R. Mayhew. Pp. x+619. (London: Longmans, Green and Co., Ltd., 1957.) 50*s*. net.

The authors have succeeded in providing the first English publication (rather than English republication of works by American authors) to give a rigorous treatment of fundamental and applied thermodynamics for the engineering student.

The first section discusses the principles of thermodynamics, and here the authors wisely follow the lines of Keenan's "Thermodynamics". They have amplified and added to Keenan's presentation. (For example, they discuss the statement of the second law for a control surface.) In general a simple lucid survey of basic thermodynamics is given, although in the discussion of the thermodynamic scale of temperature rigour has been sacrificed in the attempt to simplify the presentation.

A second section discusses "Application to Particular Fluids". Properties of fluids, non-flow and flow processes, power and refrigeration cycles, properties of mixtures and combustion processes are logically dealt with in a readable yet rigorous fashion. The section on feed heating is not as good as other parts of the book, the distinction between direct contact and surface heating not being adequately developed.

Components used in thermodynamic cycles are discussed in two sections on work and heat transfer. In their discussion of turbo-machinery, the authors point out the limitations of the so-called 'diagram efficiency' or utilization factor (in that the exhaust kinetic energy is used in most turbine stages). It is unfortunate that they do not develop definitions of turbine and compressor efficiency in terms of stagnation states, which are but briefly discussed in the section on isentropic flow.

It is pleasing to note that the heat transfer section is competently and thoroughly written.

If the division of the material into the four sections is somewhat artificial, if the book is a little too wordy and is slightly uneven (the omission of the subject of availability and the inclusion of detailed discussion of turbulent shear flows are examples of this), these are but very small criticisms in comparison with the fine overall achievement this book represents. The authors are to be congratulated on writing an excellent book, for student and teacher, and the publishers are to be congratulated on producing it at a reasonable price. J. H. Horlock

Microdiffusion Analysis and Volumetric Error

By Prof. Edward J. Conway. Fourth revised edition. Pp. xviii+465. (London: Crosby Lockwood and Son, Ltd., 1957.) 42*s.* net.

ONE may speculate as to the extent to which microdiffusion analysis is practised, but there can be little doubt of the existence of a widespread interest in the subject. This fourth revised edition of Prof. Conway's book contains accounts of many new applications of microdiffusion analysis as well as enlarged and revised sections on the apparatus used and the principles involved. New methods described include determinations of blood ammonia, total nitrogen, using a mercury catalyst, glutamine, enzymes, including acetylcholinesterase, formaldehydogenic steroids, a group of volatile poisons, and organically bound halogens. A description is also given of the method of Burbridge, Hine and Schick (1950) for the determination of acetaldehyde in blood. It may be mentioned that recent work by Lundquist published since the appearance of the work under review throws doubt on the specificity of this method. Acetoacetate in the blood may, under the conditions of the analysis, give rise to amounts of acetone which interfere in the measurement.

Part 3 of the book, a section of about 100 pages, deals with volumetric error. An analysis of the errors of micro methods compared with macro volumetric methods reveals many of the reasons which make micro work a practical possibility.

The book is clearly written and well printed. It should be read not only by those who have an immediate interest in microdiffusion but also by all who use volumetric methods of any kind. Most of the text shows an intimate practical knowledge of the processes described and no analyst could fail to profit from a study of it. The author is not always orthodox in his opinions, but where controversial issues are raised, all the evidence and the opinions of others are clearly and fairly given. The book is well illustrated and has a good bibliography and index.

E. I. JOHNSON

Introduction to the Mechanics of Stellar Systems

By Rudolf Kurth. Pp. ix+174. (London and New York: Pergamon Press, 1957.) 55*s.* net.

THIS book is intended to serve as an introduction to the subject for advanced students. After a discussion of the observational data, chapters are devoted to the mechanics of systems of mass-points, stellar systems as assemblies of gravitating mass-points, stellar systems as gravitating continua, and statistical mechanics of stellar systems. The book as a whole is written from a refreshingly novel point of view, and there is relatively little overlap with other text-books on the subject. Especially noteworthy are the treatments of the recurrence theorem of Poincaré, the little-known theorems of Hopf, similarity transformations and Poisson's equation. Although a study of the book would be of considerable educational value to an advanced student, it would nevertheless give a very one-sided view of the subject without a supplementary study of its more practical aspects. The possibility that the observations of stellar motions in our own Galaxy should be interpreted not as properties of an almost stationary stellar system but as well-preserved evidence of initial conditions during the formation of the Galaxy suggests that much of the book may remain of academic interest only. The reviewer feels that the kinematical rather than the dynamical approach to the study of stellar systems may well prove to be more fertile for further development. Nevertheless, it is important to appreciate the achievements of the dynamical approach as well as its limitations, and this book serves as a useful aid to this end.

R. H. GARSTANG

Cytochemical Methods with Quantitative Aims

Biophysical and Biochemical Approaches. Proceedings of the Symposium held September 27–29, 1956, by the Institute for Medical Cell Research and Genetics, Karolinska Institutet, Stockholm, Sweden. Edited by Dr. B. Lindström and Dr. R. Brown. (Experimental Cell Research, Supplement 4.) Pp. viii+296. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1957.) 9.50 dollars.

THIS is a report of a conference held at the Karolinska Institute, Stockholm, in September 1956, which was sponsored by the Institute of Medical Cell Research and Genetics. It consists of twenty-seven papers on different aspects of quantitative cytochemical techniques, the majority of which are physical methods, based on optical, absorption and interference microscopy, and on X-ray techniques, which are taken to include quantitative autoradiography using radioactive tracers. These papers are a mine of information which will be invaluable to all workers in these fields. The chemical techniques are less exhaustively dealt with, but nevertheless some very useful discussions of the micro-determination of nucleic acids by a number of the workers in this field are included. These form a valuable addition to the information given in existing text-books. The supplement is quite reasonably priced and would form a useful addition to libraries which do not subscribe to the whole of *Experimental Cell Research.*

Introduction to Enzymology

By Alan H. Mehler. Pp. viii+425. (New York: Academic Press, Inc., 1957.) 10.80 dollars.

IN this book the author has provided an outline of the main metabolic pathways by a description of the individual enzymes and cofactors concerned. He has not attempted to provide a comprehensive review of each enzyme, with the result that rather arbitrary and sometimes inaccurate descriptions are given (for example, the section dealing with the general properties of flavins and flavoproteins ascribes a spurious ionization constant at *p*H 1·7 to flavins, and contains generalizations concerning the fluorescence, redox potentials and absorption spectra not justified by the experimental evidence available). As the book gives many references to recent publications, it is undoubtedly useful as a guide to current metabolic trends. It is difficult, however, to find any real justification for the title of "Introduction to Enzymology". Little or no discussion is devoted to the general properties and theoretical principles of enzymic catalysis; hence very few unifying hypotheses of the type valuable to a student are developed. To those people who have been awaiting publication of a book illustrating in detail the general principles of enzyme chemistry this work will therefore be disappointing. It can be recommended only as a reasonably up-to-date book on metabolism at the level of the individual enzymes. Contrary to its title, it should be of more use to the experienced investigator than to the beginner.

VINCENT MASSEY

THE BRITISH NORTH GREENLAND EXPEDITION, 1952–54

SCIENTIFIC RESULTS

By R. A. HAMILTON, O.B.E.

THE British North Greenland Expedition carried out a programme of research in Dronning Louise Land, north-east Greenland, and on the northern part of the inland ice. The scientific plans were outlined[1] before the departure of the expedition in July 1952 ; the purpose of this article is to summarize the scientific work which was carried out.

The expedition's bases were at Britannia Sø (77° 09′ N., 23° 36′ W., 229 m.) and at 'Northice' (78° 04′ N., 38° 29′ W., 2,343 m.) on the inland ice. Many journeys were made and one party made a traverse across the inland ice from Britannia Sø to the Thule district on the west coast. A general description[2] of the expedition by the leader, Commander C. J. W. Simpson, was given in a lecture to the Royal Geographical Society before Her Majesty the Queen, the expedition's patron.

Survey

An aerial survey of Dronning Louise Land had been carried out by the Geodetic Institute, Copenhagen, in 1950. Captain Hans Jensen, and after his death in an accident, Brooke[3], extended the triangulation of Germania Land which had been started by the *Danmark* Expedition and completely triangulated the whole of Dronning Louise Land. A map on the scale 1 to 250,000 is being produced by the Institute. A further aerial survey of north-east Dronning Louise Land was carried out by R.A.F. Coastal Command[4], and from this a more detailed map on the scale 1 to 50,000 has been constructed by Arnold[5].

During the traverse of the inland ice the altitude of the surface of the ice sheet was measured at intervals of about 4 km. by trigonometrical levelling[6]. Paterson and Slesser[7] have described the method of survey and estimated the standard error of the altitude of the higher stations to be 10 m.

Geology

The geologists Peacock and Wyllie made a geological reconnaissance of Dronning Louise Land and of southern Germania Land. Archæan gneisses unconformally overlain by what are believed to be representatives of the two Precambrian sedimentary groups of north and east Greenland were discovered in western Dronning Louise Land[8], separated by a structural break from Caledonian schists farther east[9]. Four metamorphic zones culminating in lower amphibolite facies have been tentatively outlined, including a broad zone of low-grade cataclastic metamorphism in the originally high-grade Archæan gneisses. In southern Germania Land, Wyllie discovered altogether higher-grade gneisses[10] which contain basic intercalations of considerable interest, and are intruded by granite in the eastern part of Saelsø. It is believed that Dronning Louise Land lies near or on the western boundary of the East Greenland Caledonian orogenic belt, and that much deeper Caledonian structures are exposed in southern Germania Land.

Meteorology

Meteorological observations were made by Hamilton and Rollitt at Britannia Sø and at 'Northice'. The 'Northice' observations have been published in full[11] and climatological summaries[12] have been made of the observations of both stations. The temperature gradient in the air one or two metres above the surface of the inland ice was determined both at 'Northice'[13] and on the traverse across the inland ice[14] by measurement of the optical index of refraction. By this method the errors caused by the diffusely reflected solar radiation on thermometers[15] are avoided.

A detailed study[16] of the synoptic meteorology of north Greenland in the midsummer period shows that the tendency for the glacial anticyclone to be established is disturbed by waves and depressions and their associated fronts which can be followed on the 700-mb. charts. A similar study of midwinter conditions is being made.

Measurements of humidity were made at Britannia Sø[17] by a lithium chloride hygrometer : the observations suggest that at low temperatures in calm weather in the dark winter, hoar frost is not deposited until the air is saturated with respect to water.

Visual observations of aurora were made at both stations, at the same time as the meteorological observations. The forms and brightness of the aurora were recorded, using the international classification ; the positions were also noted. The information was handed over to Mr. J. Paton, of the Department of Natural Philosophy, University of Edinburgh, and has been plotted on charts for each night covering the region bounded by geomagnetic latitudes 53° and 84° and geomagnetic longitudes 70° and 90° (English Channel to north Greenland). Brief analysis of these data indicates that the auroral frequency was greater than had been expected[18]. The data will be examined more fully when the collection of the information made during the solar cycle 1951–62 is complete.

Gravity

The value of gravity was determined at approximately three hundred points on the traverse of inland ice[19] with a standard error of less than 5 milligals. The results show that the Earth's crust, with its superimposed ice load, is approximately in a state of isostatic equilibrium. In the eastern part of the ice sheet, where direct determinations by seismic methods were not possible, ice thicknesses have been estimated from the values of gravity.

During the winter when the lake was frozen, Bull[20] developed a technique of measuring the depth of the lake by gravimetric methods and was able to construct a contour map of the lake bottom.

Glaciology

The expedition planned to measure the thickness of the ice sheet by seismic methods, but neither Cadd in the first year nor Bruce in the second year was able to detect reflexions from the ice – bedrock interface at any point between Dronning Louise Land and 'Northice', and it was not until shortly before the expedition was due to come back that an energy return was detected at a point farther west. Thereafter, strong reflexions were obtained west of a separating line[21] running approximately 330° through 77° N., 45° W., but no reflexions could be obtained east of it. In this region the bedrock is approximately 200 m. below sea-level. The seismograms indicate that the reflexion coefficient east of the separating line is less than one-hundredth of that at points west of it. Bull suggests that the phenomenon may be explained by assuming that the bottom of the ice is melting to the east of the separating line and that the thickness of ground moraine varies greatly across it. The altitudes of the seismic stations on the inland ice were computed[22] from the aneroid readings, by the use of meteorological upper-air charts, with an estimated error of 13 m.

In addition to measuring the altitudes of the stations on the gravity traverse, Paterson[6] also determined the surface slope of the ice sheet at a number of places. These enabled Bull[23] to calculate the shear stress on the bed from Nye's formula.. The values of shear stress in the east are lower than those in the west, and it is suggested that the difference may be due to bottom melting in the east.

At about thirty points on the gravity traverse the firn structure was examined. A Rammsonde was used for measuring the resistance to penetration which had been related to the density by a series of calibrating experiments[24] at 'Northice'. The soundings show that the mean annual accumulation for the period 1948–53 was about 13 gm./cm.^{2} and was almost constant along the gravity-traverse route, except near the coasts, where the accumulation is less, due, presumably, to increased abflation. Except near the coasts, the annual accumulation in the eastern part of the traverse for the period July 1953–July 1954 was approximately[25] 16 gm./cm.^{2}.

Beacons were erected on the inland ice and their positions, as well as the height of a mark above the snow surface, were accurately determined, so that if these are remeasured about twenty years later the mean movement of the ice sheet and the net accumulation during the period can be determined[26].

A pit dug to a depth of 14 m. at 'Northice' enabled the annual accumulation back to the year 1878 to be determined[27]. This decreased during the last part of the past century and continued to decrease to a minimum value in 1940, but has increased again in the past decade.

The regime of two glaciers in northern Dronning Louise Land was studied[27]. There was a net loss from their surfaces of less than 1 m. depth of water equivalent, most of which was compensated by flow from the inland ice. Measurements of the rate of flow indicate that it is 12–20 m. per year.

Lister and Taylor[28] studied the heat balance at the glacier surface. Of the total amount of heat which entered the glacier from above, the contributions due to radiation, condensation and eddy conductivity were 69, 2 and 29 per cent. The proportions of this total heat used in melting, evaporation and conduction into the ice were 54, 34 and 12 per cent. Similar micro-meteorological investigations were made by Lister at 'Northice', but the results have not yet been worked up.

As a result of his study of all the major glaciers of Dronning Louise Land, Wyllie[29] concludes that the decrease in the height of the inland ice and the consequent emergence of rock thresholds is the dominant factor in the final stages of glacial recession. Ice recession in the neighbourhood of Britannia Sø was studied in detail[30].

Physiology

Though the emphasis was on research in the geophysical sciences, a programme of physiological research had been drawn up by the Medical Research Council. A general account of the physiological and medical aspects of the expedition has been given by Lewis and Masterton[31]. Acclimatization to cold was the main line of research. Body-weights were measured weekly and have been compared[32] with comparable weights of intakes into the Regular Army. The annual increase of weight of the expedition members was greater than that of the soldiers and showed also a seasonal fluctuation with a maximum in the early spring. Measurements of fat thickness showed a close correlation with changes of body-weight[32]: the experiments indicated the need for simplification of the technique of measuring subcutaneous fat. The number of sites of the body was reduced from thirty-six to five[33], and subsequent work suggests that the subcutaneous fat at one site (namely, under the scapula) correlates extremely well with changes in body-weight[34].

The effect of seasonal light and darkness on the men's sleep was studied. It was found that although sleep was taken very irregularly, there was no seasonal variation in the number of hours slept in a month. The average sleep taken was just under 8 hr. per day, which may represent the natural biological demand[35].

The men's basal metabolic rate was measured fortnightly: the mean was almost identical with that given for men in Britain. The figures confirm that British means are substantially smaller than the American figures.

The physiological findings reflect the pattern of activity of the men rather than an effect of season *per se*; in any event, the body was shielded from the extremes of environment by clothes and shelter[36].

Measurements of the men's physical efficiency were made; but the results tend to be equivocal. Diurnal temperature measurements remained within normal limits and the blood cells were found to remain constant; there was no rise in the red cell count in men who were subjected to the 2,500 m. altitude of the inland ice. These findings indicate the great stability of many body systems in spite of great fluctuations in the external environment.

Research was also carried out in the nutritional field. By way of experiment, samples of biltong were taken for eating on journeys: its use stimulated a fuller investigation into its calorific value[37].

The observation that husky dogs eat human fæces prompted an investigation which revealed that the fæces did not contain excess fat[38]. This in turn suggested a full investigation of the calorie requirements of men sledging[39]. There were wide variations, from 4,000 to 5,500, with a mean of 4,800 calories a day. An estimate of energy expenditure tallies very closely with this figure, confirming that the food intake was just adequate.

This research has a two-fold significance. First, it has formed the nucleus of subsequent polar physiological programmes of Antarctic expeditions now in the field. The second feature is the fact that our figures show the sledging ration of 4,200 calories to be insufficient to maintain nutritional balance in the face of extremely hard work in the cold. The Medical Research Council reviewed the whole problem and advances in food technology packaging have been incorporated in prototypes now being tested in the polar regions[40].

On the biological side, the incidence of trichinosis in those dogs which were shot or died in the second year were studied. It was found that the infested dogs were among those which had been brought from west Greenland, where they have been accustomed to eating raw meat, while none of the puppies which had been born on the expedition were infested[41].

The insects which were collected in the Britannia Sø area and placed in the British Museum are all well-known members of the Arctic fauna of Greenland[42]. A botanical collection has been examined by Dr. A. Melderis at the European Herbarium of the British Museum, where the specimens are now lodged.

Small fish, an unusual variety of the Arctic char, *Salvelinus alpinus*, were taken from Britannia Sø and handed over to Mr. G. F. Friend, of the Department of Zoology, University of Edinburgh. These fish are undoubtedly descendants of migratory sea-char which once made their way up a river, into the lake, and established themselves there. Since then, they have been isolated for thousands of years perhaps, and have evolved their own peculiarities, some probably in response to their difficult life in high latitudes and sealed as they are for five-sixths of the year under thick ice. Their eyes, nostrils and lateral-line pores—all sense organs—are large for the size of such small fish. They have a starved and juvenile appearance, while their growth-rate is slower than that of any known race of char. A low, flattened cranial-roof and a 'turtle nose' are other striking features. These add much new material to the picture of the chars as a whole.

Except where stated above, the results of the research carried out in the field have now been worked up and the following list of publications may be regarded as the scientific results of the expedition.

COLONIAL RESEARCH, 1956-57

FOLLOWING the pattern of the previous report, under the title "Colonial Research, 1956–57"[*], are collected the annual report of the Colonial Research Council, the twelfth annual reports of the Committee for Colonial Agricultural, Animal Health and Forestry Research and the Colonial Medical Research Committee, the tenth annual reports of the Colonial Economic Research Committee and the Colonial Pesticides Research Committee, the fourth annual report of the Colonial Products Council, the thirteenth annual report of the Colonial Social Science Research Council, the second annual report of the Colonial Road Research Committee, the annual reports of the Colonial Fisheries Advisory Committee on Fisheries Research, 1956–57, of the Tsetse Fly and Trypanosomiasis Committee, and of the director, Anti-Locust Research Centre. There is also a section on research matters not covered by the reports of the specialist advisory bodies, which deals with building and housing research, the Falkland Islands Dependencies

---

[*] Colonial Office. Colonial Research, 1956–1957: Reports of the Colonial Research Council; Committee for Colonial Agricultural, Animal Health and Forestry Research; Colonial Economic Research Committee; Colonial Fisheries Advisory Committee; Colonial Medical Research Committee; Colonial Pesticides Research Committee; Colonial Products Council; Colonial Road Research Committee; Colonial Social Science Research Council; Tsetse Fly and Trypanosomiasis Committee; Director, Anti-Locust Research Centre; and Research Matters not covered by the above Reports of the Specialist Advisory Bodies. Pp. 322. (Cmnd. 321.) (London: H.M. Stationery Office, 1957.) 11*s*. net.

Survey (an outstanding feature of the work of which has been the air survey of 35,000 square miles conducted during the past two years by Huntings Aerosurveys), meteorology, industrial and engineering research, water-pollution research and geodetic, topographical and geological surveys. For the first time in many years, recruitment of surveyors and cartographical draughtsmen exceeded losses and the total staff on March 31, 1957, was 390, while the number of geologists, geophysicists and geochemists overseas, where geological surveys continued in twenty territories, rose to 211, although some vacancies remained unfilled.

Other than the fact that the work is concerned with problems arising in various overseas territories there is little in common between the several reports, nor is any general conspectus attempted even in that of the Colonial Research Council itself, other than the brief reference to Colonial Development and Welfare Schemes (a list of which is appended to the report). Expenditure on these schemes for the year ended March 31, 1957, was £1,538,412, compared with £1,374,323 in the previous year. A review of the whole field of Colonial research where Colonial Development and Welfare assistance is involved is being undertaken, and the Council will then consider the possible re-allocation of funds between the various fields to ensure that full use is made of remaining funds under the current Colonial Development and Welfare Act to fulfil the various programmes envisaged. Even this, however, gives no true measure of the effort in Colonial research which Britain is making. As the various reports demonstrate, this effort is interwoven with that made by the various overseas Governments themselves, and with that of British as well as Colonial universities, so that a complete assessment is difficult or impossible. Apart from the financial aspect, it represents an appreciable tax on British scientific and technical man-power which the universities and research institutions must be prepared to meet. During the year, thirty-four new appointments brought the complement of the Research Branch of the Overseas Civil Service in March 1957 to 189. In addition, two Research Fellows continued investigations on behalf of the Colonial territories, and fourteen research studentships were awarded.

The Committee for Colonial Agricultural, Animal Health and Forestry Research, which recommended grants totalling £925,921 during the year, still finds difficulty in securing suitable officers for senior posts, although recruitment of scientific staff for overseas duties was a little easier. To ensure closer co-ordination of work on control of pests and diseases, a special sub-committee, the Crop Protection Sub-Committee, was set up jointly with the Colonial Pesticides Research Committee. Under the Technical Aid Agreement, the Food and Agriculture Organization gave expert assistance for surveys of the Rufiji Basin in Tanganyika and the Accra Plain in Ghana, assisted Cyprus in controlling an outbreak of sheep-pox, and provided an expert for a survey of swamp soils in Sarawak. Acknowledgment is again made of the help received from research organizations and universities in the United Kingdom.

Much of the work of the Commonwealth Institute of Entomology is concerned with Colonial problems and 42 per cent of the Institute's identifications during the year were concerned with Colonial inquiries, notable help being given to a survey of forest pests in East Africa and to the investigation of premature nutfall of coconuts in the British Solomon Islands Protectorate. Very satisfactory progress has been achieved in Jamaica with soil surveys, the results of which are being utilized in land rehabilitation schemes in overcrowded areas, while studies on soil fertility are receiving very close attention in nearly all Colonial territories. There is good prospect of remedying the deficiency of major and minor plant nutrients which prevent good growth of crops over large areas of Africa south of the Sahara. The Herbarium of the Commonwealth Mycological Institute is collaborating with the West African Maize Research Unit in a statistical analysis of spore sizes in collections from different parts of the world, and a serious outbreak of leaf-curl disease in flue-cured tobacco in Nigeria led to a recommendation for an immediate preliminary survey of economic-crop diseases. An electronic computer was used in a theoretical investigation for the Tsetse Fly and Trypanosomiasis Committee into the effect of introducing sterilized males into a natural tsetse fly population.

It appears that research results are increasingly being applied in tropical agriculture. Extension of soil conservation measures with the concomitant practice of moisture conservation in areas of low or erratic rainfall has greatly improved farm conditions in Kenya, Swaziland, Uganda, Granada and Somaliland. The soil nutrient status has also become clearer with discoveries of deficiencies of major and trace elements in many parts of Africa, particularly of phosphorus, nitrogen, sulphur, boron and molybdenum. Maize breeding in Africa, particularly with strains from Mexico, has produced a series of high-yielding varieties highly resistant to tropical maize rust, while cocoa hybridization in the West Indies and West Africa has given new material of exceptional yield and early bearing. Organic weed-killers also figure prominently in research programmes: thus, in West Africa a programme to spray 700,000 acres against capsid has been approved, of which about 100,000 acres have been treated with power-sprayers, and about 20,000 hand-sprayers have already been sold to cocoa farmers. Considerable advances have been made in the control of pests and diseases of cotton, and practical and economic measures developed for controlling major insect pests of sorghum and other cereals. Much attention is being given to the prevention of damage by storage pests and valuable advances are being made in control or prevention, particularly with rice, cocoa and groundnuts.

The large regional research organizations have advanced fundamental knowledge of the role and importance of organic matter in tropical soils, the nitrogen and sulphur cycles and phosphate fixation. Advances in banana breeding are recorded in the West Indies and the examination and description of flora continued in East Africa, the Zambezi Basin, Cyprus, Malaya, Tropical West Africa, Jamaica and Trinidad. Particular attention was given to the co-ordination of research and the prompt exchange of information between workers in allied fields. In forestry the cultivation in plantations of the valuable African timber tree, mvule (*Chlorophora excelsa*), was specially examined in collaboration with the Imperial Forestry Institute. Work on hormonal arboricides has established their use in eliminating weed trees when making improvement fellings, and notable success has attended species trials on tropical pines in Central Africa and the Caribbean, and work on ambrosia beetles in West Africa has led to the adoption of practical measures of control. While attention to animal breeding led to no spectacular results, stock of better quality is continually becoming available and progress in vaccine production and other biological products has permitted a high degree of control of rinderpest and pleuropneumonia of cattle and Newcastle disease of poultry, and much progress was made in fundamental work on protozoal diseases of animals in East Africa. The detailed accounts of the work of the regional organizations include lists of publications. The Committee's report now occupies some 111 pages out of a total of 322.

The tenth annual report of the Colonial Economic Research Committee records the completion of Prof. A. T. Peacock's inquiry on the national income of Tanganyika, and of Mr. D. T. Edwards's analysis, in association with the Jamaican Department of Agriculture, of the economics of small farms in Jamaica. A large-scale study of the economics of farming systems in Africa was commenced and also an investigation of the agricultural economy of Malta. Among new projects priority was given to a study of the economics of road development in Uganda; an economic survey of the Seychelles; a survey of farm production in British Honduras; studies of the Fijian community as an economic unit; and of the effects of diamond mining in Sierra Leone on a predominantly subsistence economy.

The annual report on Fisheries Research, 1956–57, which comprises the reports of the individual Colonial fisheries research stations, records the failure of a special mission to impress on local opinion in Ghana and Nigeria the continuing need for fishery research in West African waters and the consequent winding-up of the West African Fishery Research Institute, Sierra Leone, as an interterritorial body, though plans have been laid to safeguard the results already obtained by establishing, in consultation with the Sierra Leone Government, a small territorial unit based on the Institute's premises. Both the Federation of Malaya and the Singapore Government have withdrawn from the work of the Regional Fisheries Research Station at Singapore, and this station is also to be wound up. Efforts are being made to place the scientific staff of both stations in other parts of the Oversea Research Service.

Results obtained at the Jinja laboratory of the East Africa Inland Fisheries Research Organization have been used in advising the East African Governments on the probable consequences of proposed changes in legislation for the protection of fish stocks in Lake Victoria. Experimental evidence has now shown that organic sulphur deposited on the lake bed as plant debris has little chance of being converted into available sulphates. Interest in snails as intermediate hosts has led to the observation that the ability of snails living in small streams and pools to survive the dry period depends on their degree of infestation by parasitic nematodes. The effects of DDT on insectivorous fishes have been studied, and work on the food and feeding habits of insect-eating and fish-eating species of fish in Lake Victoria is nearly complete. Steady progress is reported by the East African Marine Fisheries Research Organization, which has correlated the seasonal appearance of the dolphin-fish, *Coryphaena hippuris*, with plankton and hydrographic data.

The Northern Rhodesian–Nyasaland Joint Fisheries Research Organization gave priority to basic research on fish ecology in Lake Bangweulu, the Bangweulu swamps (where the importance of *Vossia* grass is being studied) and the Zambesi and Ianyeti rivers in the area to be covered by the Kariba Dam. From the Fisheries Research Unit, University of Hong Kong, a hydrographic survey of the sea around Hong Kong has now continued for two years and the possibility of developing an edible-oyster industry in Tolo Harbour has been investigated. The West African Fisheries Research Institute had fifteen scientific papers published or in preparation, including a complete scientific survey of the Sierra Leone estuary and an extensive survey of the bottom fauna on the continental shelf off Freetown, correlating this fauna with the nature of the sea-bed and with the food of fish.

The twelfth annual report of the Colonial Medical Research Committee refers to the termination of research on the physiology of hot climates which, in Nigeria and adjacent territories over the past eight years, has been very productive. With this exception, the various fields of research have remained unchanged, although research on trachoma in Jordan had to be suspended. The Research Unit on Tuberculosis in Ghana is now well established and has maintained effective contact with workers in Nigeria and Sierra Leone, while the formation of the Leprosy Sub-Committee has greatly stimulated interest and co-ordination; pilot control measures based on data secured in filariasis research, whether loiasis or bancroftiasis, are increasingly applied or planned. On the recommendation of the Committee, modest block grants have been placed at the disposal of each of the three regional organizations for medical research, in East and West Africa, and the British Caribbean, from which each could make small immediate grants annually to provide some additional research facility required by an individual research worker.

Research on loiasis and onchocerciasis in the Cameroons and Nigeria indicated that use of DDT and dieldrin granules in high concentrations (say, 5 per cent) to spray the mud of breeding-sites of *Chrysops* and *Tabanus* killed all larvæ, a process which, while very costly, may be economical in the rain-forest where the breeding-sites, though scattered and inaccessible, are small in total area. Investigations into the effects of 'Antrypol' and dimercaptosuccinate on the concentration of microfilariæ in onchocerciasis gave promising results. Encouraging results were also obtained in East Africa in the control of filariasis in rural areas by treatment with 5 mgm./kgm. 'Hetrazan' once a week for six weeks and by spraying houses with dieldrin at 100 mgm./ft.^{2} every six months. A pilot control scheme of bilharzia among schoolchildren is to be undertaken in the Mwanza area. Investigations on guinea-worm at University College, Ibadan, point to the value of 'Hetrazan' as a prophylactic for travellers journeying through endemic areas of dracontiasis, while in Tanganyika granulated dieldrin has proved a highly effective larvicide.

No definite evidence of a relation between the frequency of the sickle-cell trait and the parasite-rate or parasite-density was obtained in investigations in Nigeria and Southern Cameroons on malaria and the sickle-cell trait. At the West African Council for Medical Research Laboratories, Lagos, studies in hepatic pathology showed that monkeys hyperimmunized against Zika virus were more tolerant to the yellow fever virus than the normal controls, while at the Trinidad Regional Virus Laboratory, Port of Spain, research has centred around epidemiological investigations of Ilheus virus infections. Investigations on the yellow fever hazard at the Institute for Medical Research, Kuala Lumpur, have been mainly concerned with whether local mosquitoes and animals can transmit and maintain the disease, whether the presence of other viruses in Malaya would affect its establishment, and methods of vaccination and mosquito-control. The United States Army Medical Research Unit (Malaya), in collaboration with the Institute, the nearby British Military Hospital and the Walter Reed Army Institute of Research, Washington, has made clinical and laboratory studies of children with pyrexias of unknown origin in the General Hospital, Kuala Lumpur, of encephalitis in Singapore and the Federation, and of the ecology of potential vectors of viral diseases in Malaya.

Much progress has been made in building up facilities for nutrition research at the East African Medical Survey and Research Institute, Mwanza, and at Kampala the Infantile Malnutrition Research Unit continued to explore the use of various diets in treating kwashiorkor. The Tropical Metabolism Research Unit, Jamaica, continued work on the composition of tissues in malnutrition, especially of muscle, and some progress was made in the measurement of Krebs cycle oxidations. In a controlled pilot trial in Nigeria, which has now lasted twenty-five months, diphenylthiourea has proved an effective treatment for all types of leprosy in a dosage of 1·0–3·0 gm. daily. It is at least as active as diaminodiphenylsulphone. With an isoniazid it combines effectively, is remarkably free from toxic action, and no evidence of drug resistance has appeared. Diaminodiphenyl sulphoxide also continues to show considerable promise. In studies at Makerere College on the enzymes of *Mycobacteria*, particularly the use of tetrazolium salts to detect dehydrogenases, satisfactory micro-methods have been developed which give consistent results with cultural organisms. At the National Institute of Medical Research studies have been made on the evolution of infection with *Mycobacterium lepramurium* in experimental animals, while at the Medical Research Council Laboratories in The Gambia, observations on the long-term therapeutic effects of 'Hetrazan' in *Wuchereria bancrofti* infections indicate that the maximal effect of non-toxic dosage-levels is not discernible until two years after treatment. In research on the biology of sandflies in East Africa, work with *Phlebotomus guggisbergi* may provide clues as to the real vector of kala-azar.

The tenth annual report of the Colonial Pesticides Research Committee refers to further studies of the Colonial Insecticides Research Unit, Porton, on the sorption of insecticides by soils, which have shown that repeated sprayings do not affect the sorption-rate, whereas increase of temperature increases the sorption of DDT and dieldrin, and that loss of insecticide by chemical decomposition is not a significant factor. A preliminary investigation has been made of the properties of residual DDT and dieldrin on some surfaces used in house construction, and the relative toxicities of the organic phosphorus insecticides, diazinon, chlorthion and malathion, to houseflies and some species of mosquitoes have been determined. Promising new variations in olfactometric technique have been developed at the Imperial College Field Station, Silwood Park, while at Long Ashton Research Station a technique has been evolved for controlling leaf-spot disease of Lacertan bananas. At Urambo, Tanganyika, the Colonial Pesticides Research Unit successfully controlled heavy infestations of bollworm (*Heliothis armigera*) and stainers (*Calidea*) on cotton by weekly sprayings of DDT at 1 lb./acre, with BHC for aphid control when required. Control of bean fly, *Agromyza* (*Melanagromyza*) *phaseoli*, has been obtained with seed dressings of emulsifiable concentrates of aldrin, endrin and dieldrin. The Biting Fly Research Unit, Uganda, extended its facilities for entomological research and has established a laboratory colony of *Stomoxys calcitrans*. In filariasis research in Fiji residual sprays of DDT and dieldrin gave satisfactory control of mosquitoes resting in houses, and in transmission experiments high infection-rates were obtained with *A. polynesiensis* Marks in feeding experiments. In the Western Sokoto Malaria Control Pilot Project an improved technique for sampling insecticide deposits on mud surfaces was evolved, and on the 100-acre experimental plot at Kidichi Mdo, Zanzibar, effective economical control of *Pseudotheraptus wayi* on coconuts was obtained using 10 per cent DDT with 1 per cent coumarone indene resin dissolved in a mixed aromatic petroleum solvent.

Stress is also laid on research being done in the Colonies without the assistance of the Committee: for example, the preliminary survey at Aden of the relative importance of various pests of cotton; the promising results obtained in control of various weeds in Bermuda; the control of olive leaf spot (*Cycloconium oleaginum*) in Cyprus with 10 : 1 : 100 Bordeaux mixture; of scale insects on *Hibiscus* sp. in Malaya with dieldrin and 'Nicotox'; and of white copper borer, *Anthores leuconotus* Pasc., with 0·5 per cent dieldrin in Tanganyika.

Almost half the fourth annual report of the Colonial Products Council and Laboratory is concerned with work conducted outside the Laboratory but under the direction or with the assistance of the Council. The 745 inquiries handled by the Laboratory during the year, of which sixty-two were still in hand, included such varied subjects as cedarwood oil, coconut products, the development of *Crambe abyssinica* as an oilseed crop, the relative nutritional value of *Oryza glaberrima* and *O. sativa*, the packing and transport of fresh mangoes, nutritional biscuits from local ingredients for school-children in Uganda, and the extraction of vitamin C from the West Indian cherry. Among the ninety-five investigations completed by the Laboratory during the period were those relating to oil of *Leptospermum citratum*, oil from the bark of *C. pedatinervium* as a source of safrole, Illipe butter, sugar cane wax, sisal wax, starches from arrowroot and sago, and animal feeding stuffs from waste materials. Other work included the separation, by chromatographic and counter-current techniques, of the constituents of pyrethrum, work on the seaweed *Corallopsis opuntia*, which has good jellying properties, the comparative properties of abaca fibre from Borneo, Sumatra and the Philippines, and pulping trials of *Ricinodendron rautanenii* timber from Northern Rhodesia and of British Honduras slash pine, *P. caribaea*.

Further work on the curing of the cacao bean and on the structure of the cacao leucocyanidin compounds was carried out at the Colonial Microbiological Research Institute, Trinidad, where a 3 : 4-diol structure has been indicated for peltogynol in place of the accepted structure, and the isolation of the intermediate oxidation products of substituted catechols is in progress. The Sugar Technological Laboratory, Trinidad, carried out much work on the fundamental physico-chemical aspects of clarification and also further work on the removal of evaporator scale and the chemistry of constituents of ammoniated molasses, but pilot-plant work indicates that the production of lævulinic acid from molasses is unlikely to be economical. At Makerere College, besides investigations on the natural products of East African plants, the methane fermentation of vegetable wastes has been studied up to pilot-plant scale; and studies at the Forest Products Research Laboratory, Princes Risborough, on the production of fibreboard from secondary Colonial timbers indicated that after treatment with steam alone in the 'defibrator', pulp from all the species tested required further refining to give boards of adequate strength. Work on sugar derivatives continued at the University of Birmingham, where the series of oligosaccharides produced by acid reversion of N-acetyl-D-glucosamine has been fractionated and two disaccharides isolated, and a unit has been established for studying the pharmacological activity of extractives from plants and other materials of interest to Colonial territories. The study of medicinal plants which might contain hepatoxic agents by the Medical Research Council's Toxicology Research Unit continued and also work on the constitution of the alkaloid dioscorine at University College, Cardiff, chemical investigations on the leaves of *Anona senegalensis* and the structure of the pectic compounds of *Agave sisalana* flesh at the University of Edinburgh. Further investigation at the Institute of Animal Physiology, Cambridge, of extracts of the seeds of *Dichapetalum toxicarium* indicates that a major part of the active fraction behaves mainly as a C_{18}-fatty acid with one double bond and one fluorine atom.

In its second annual report the Committee on Colonial Road Research notes a slow but steady build-up of the Colonial Section of the Road Research Laboratory, which, at the end of March 1957, was short of its complement by two scientific officers, five experimental officers and five assistants (scientific) and emphasizes the adverse effect of the restrictions and delays in new buildings. Federal Nigeria proposes to establish its own central Road Research Laboratory, and Western Nigeria and Northern Nigeria are building up their Materials Testing Laboratories. Research teams have been recruited to study road-making materials available in Colonial territories and pavement design, and a survey has been made of published information on corrugations, theories advanced to explain their formation, and on methods of alleviating or preventing them by selection and treatment of road-making materials.

The bearing capacity of representative soils from Uganda, Northern Rhodesia and The Gambia over a range of densities and moisture contents has been determined using the California bearing ratio test. Road construction problems with fine-grained cohesionless sands occurring in coastal and desert areas have been investigated in connexion with the proposed Ado–Badagry road in Western Nigeria and the Georgetown–Rosignol road in British Guiana. A range of full-scale experiments on the use of rubber in surface dressing, bitumen macadam and rolled asphalt is in progress, and examination of the economics of roads and road transport in under-developed territories has begun. This work has included a review of methods of road accidents with the view of helping territories to adopt methods within their capacities and suited to their needs, and ensuring that the data are so presented that they provide a reliable measure of the pattern of road accidents and their economic importance.

To the thirteenth annual report of the Colonial Social Science Research Council are appended the customary reports for 1956–57 of the East African Institute of Social Research, the West African Institute of Social and Economic Research, the Institute of Social and Economic Research, University College of the West Indies and the Rhodes–Livingstone Institute. Work was commenced on the project initiated at University College, Ibadan, for a history of Benim, to be financed jointly by the Carnegie Corporation and the Governments of Nigeria, and a study of family attitudes in Jamaica. The fourth volume, "Bantu Languages of Africa", of the Handbook of African Languages is in the press, and forty volumes of the Ethnographic Survey of Africa have now been published, while further sections on peoples of East Africa and of Nigeria are in preparation. A new relation between the East African Institute of Social Research and the Social Studies Department of Makerere College is being inaugurated which will establish a closer link between teaching and research, while maintaining the Institute as an autonomous organization within the College. The Institute of Social and Economic Research, University College of the West Indies, is studying West Indian agriculture and agricultural development, the labour market, the analysis and supplementation of West Indian national accounts and the role of investment in economic development. At the Rhodes–Livingstone Institute for Social Research, studies are in progress of European communities in the Copperbelt and in Southern Rhodesia; of the economics of peasant farms and of African education; and of urban sociology and the sociology of industry as well as two tribal studies.

The major field of activity of the Tsetse Fly and Trypanosomiasis Committee was in chemotherapy, and at a conference at the Colonial Office agreement was reached on procedures for the fullest co-ordination of full trials of promising new trypanocidal drugs and the prompt dissemination of such results. The new procedures have already been implemented, and the suramin complexes developed at the West African Institute for Trypanosomiasis Research appear to offer a considerable increase in the period of protection obtainable. In human trypanosomiasis the Institute has closely studied changes occurring in the saliva of tsetse infected with the *brucei* group of trypanosomes, and its clinical trials indicate that 'Malarsen' is a valuable alternative for treating *T. gambiense* infection under field conditions, especially in late or relapsed cases. Research on the forest species of tsetse continued at the Field Station and a comparative experiment on 'man–fly contact' was started near Kaduna during the rains. The study, by the East African Trypanosomiasis Research Organization, of the resting-places of the tsetse flies *Glossina swynnertoni*, *pallidipes* and *morsitans* is likely to lead to new ideas on the use of insecticides. An investigation of the mechanism of water control in the pupa of *Glossina* is contributing to an understanding of the success and failure of some current methods of reclamation.

At the Sukulu Laboratory a small hospital was opened for the reception of patients from the lakeshore fly-belts, and a joint investigation with the Kenya Medical Department has shown that in that area *G. pallidipes* is a carrier of *T. rhodesiense*. The epidemiology of *palpalis*-borne sleeping sickness in Uganda is also being investigated. In Northern Rhodesia trypanosomiasis research has been limited to drug trials and prophylaxis. The Veterinary Department of the Northern Region of Nigeria is pursuing a vigorous programme of research into cattle trypanosomiasis, while the Department of Veterinary Services, Tanganyika, has compared the protection given by prothidium, ethidium–suramin complex and *RD*290 suramin complex with that given by 'Antrycide' prosalt. Prothidium was also the outstanding new prophylactic tested by the Department of Veterinary Services, Kenya.

The report of the director of the Anti-Locust Research Centre for 1956–57—in which the Centre received 984 reports of the desert locust situation from thirty-two territories, including reports on low-density locust populations from survey officers in the Somali Peninsula, Ethiopia and parts of Arabia—notes that the desert locust situation improved somewhat in Eastern Africa, Iran, Pakistan and India, although heavy breeding occurred in the Sudan, the French Chad territory and the Niger Colony. A panel of international experts which met at the Anti-Locust Research Centre in April 1956 recommended that permanent surveys of the whole of the distribution area should be established by all governments concerned, and that all information on the state of desert locust populations and relevant weather phenomena should be centralized.

The International Red Locust Control Service continued studies on red locust populations in relation to vegetation dynamics and on control methods, and the International African Migratory Locust Organization became a permanent international body in 1956, when a research service was established. The Anti-Locust Research Centre continued to work on phase variation and its inheritance; maturation and fecundity in the red locust; weight and water-content of the desert locust in relation to flight and the life-cycle of *Eyprepocnensis plorans*, *Acrida bicolor* and *Gastrinargus africanus*. Annual and seasonal frequency maps of the incidence of desert locust swarms and hoppers were completed and maps of the major seasonal swarm movements were prepared.

OBITUARIES

Dr Willis R. Whitney

With the death on January 9 of Dr. Willis Rodney Whitney, at the age of eighty-nine, there ended a very remarkable career.

Although Dr. Whitney was a first-class scientist in his own right, his great contribution was the organization and successful direction, for thirty-two years, of the Research Laboratory of the General Electric Co., Schenectady, New York. It is hard to understand now what a truly pioneer task this was, for in 1900 there were no organized industrial research laboratories in the United States. He had to prove that industrial research could be made to pay. When he did this, other industries quickly followed General Electric's example. To-day, a research laboratory is considered essential for industrial success.

Born in Jamestown, New York, on August 22, 1868, Dr. Whitney's interest in science began with the acquisition of a microscope when he was in high school. After graduating from the Massachusetts Institute of Technology in 1890, he first spent four years as instructor in chemistry there, then went to the University of Leipzig, where he received his Ph.D. degree in 1896. After six months at the Sorbonne, he returned to the Massachusetts Institute of Technology as assistant professor and later full professor.

It was at this point that E. W. Rice, vice-president of the General Electric Co., visited him and proposed that he should start a research laboratory—a thing new to industry. The fact that it was an experiment appealed to Whitney—he loved an experiment. But he also believed in proceeding cautiously and slowly, feeling one's way. So he agreed to try it on a part-time basis, spending three days a week in Schenectady and the other three at the Massachusetts Institute.

His first laboratory was a barn in the rear of Dr. Steinmetz's house, and the laboratory staff consisted of Whitney and half the time of an assistant shared with Dr. Steinmetz. When the barn burned down in the following year, he moved to a building in the Schenectady works, and gradually began to add more employees, being very careful to preserve the atmosphere of friendly co-operation.

This atmosphere he himself generated by personal example. As long as the size of the laboratory permitted, he made a practice of visiting every member of the staff every day. His usual greeting on these visits was, "Are you having any fun ?". To him, research was fun, "the finest of sports", as he once expressed it. Frequently, on his visits, he brought some new project or experiment, suggested by company activities or scientific progress, which he literally peddled from room to room, but seldom assigned.

It was one of his key principles that members of his staff were given freedom, in proportion to their proved ability, to choose their own research problems, and to publish important results promptly in their own names. He was a pioneer in the championing of such publication.

Optimism, enthusiasm and sound judgment were conspicuous qualities of Dr. Whitney, but above all was his devotion to science. It was literally true of him that science was his religion. He often talked about religion, but always concluded that the "search for truth" was the best kind of religion.

Scientific curiosity, which he once defined as the greatest asset of a research man, was his most conspicuous quality. If you visited him on a Saturday afternoon, you were likely to find him in a field near his home, putting a small piece of iron wire in the stem of a golden-rod and surrounding it by a high-frequency coil, to find out whether it was the heat of the bug inside that caused the swelling called a gall to grow. Or you might find him sitting on a log in the woods, counting the mosquitoes that alighted on him and on a quarter of beef beside him, to find out how they knew what to bite.

Dr. Whitney retired as director in 1932, becoming an honorary vice-president of the General Electric Co. But he still came to the laboratory every day, at first devoting his time to personal experiment, his first love, which he had missed during his directorship; and later to visiting the research workers, with interest and encouragement.

Dr. Whitney's success as a pioneer of industrial research is a lasting contribution. The secret of that success was a combination of remarkable personal qualities—friendliness, mental vigour, breadth of interest and knowledge, stimulating originality, delightful flashes of humour, modesty, courage, directness and simplicity. A. W. HULL

Dr. K. H. Barker

DR. K. H. BARKER, who died suddenly in London on March 3, was born in Manchester in 1925 and educated in the Department of Physics at the University of Manchester, graduating in 1948. His university education was interrupted between 1945 and 1947 when he worked on the Tube Alloys Project in the Department of Physics at the University of Liverpool.

In 1948 Barker started research work in cosmic-ray physics at Manchester, under the direction of Prof. P. M. S. Blackett. At the beginning of his research career he joined my group, then engaged in studying high-energy nuclear collisions using a cloud chamber equipped with an electromagnet. This collaboration lasted until his death, a period of almost ten years without a break. His death is a very great loss to the group and to the subject of high-energy nuclear physics in which he had achieved a world-wide reputation.

The Manchester electromagnet was moved to the Observatory on the Pic-du-Midi in the French Pyrenees in the autumn of 1949. Barker was responsible for installing the magnet and cloud chamber in the mountain laboratory at an altitude of 9,500 ft. Altogether, he spent between two and three years of his life working with the apparatus. In the early years he often climbed to the mountain top during the winter months; but a cable railway has now been installed. Barker was a first-class experimental physicist able to operate and maintain efficiently a complicated piece of equipment in very difficult circumstances.

In 1950 Barker obtained a very valuable set of photographs showing many decays of V^0-particles. From the analysis of these pictures the group demonstrated, for the first time, that the V^0-particles, discovered by Rochester and myself in 1947, consisted of two kinds: neutral Λ-hyperons which are heavier than the proton and heavy mesons, with mass intermediate between the π-meson and the proton. Barker played a leading part in obtaining and interpreting these photographs. He also observed, in 1950, the first decay of a Ξ^--hyperon.

In 1953 Prof. Blackett and a number of his staff moved from Manchester to the Imperial College of Science and Technology, London. Barker was at once appointed a lecturer in physics at the Imperial College and continued to spend part of his time at the Pic-du-Midi working on the same general research programme. During the past year or so the group has been studying the properties of nucleon–nucleon collisions with energies of 50 GeV. and upwards. In this work Barker collaborated very successfully and fruitfully with French physicists from Prof. Leprince-Ringuet's Laboratory at the École Polytechnique in Paris. At the time of his death he was enthusiastically planning new experiments in high-energy nuclear physics using an accelerator, instead of the cosmic-rays, as a source of particles.

Barker was a good teacher, both of undergraduates and research students, and, as a friendly and helpful colleague, will be sadly missed by the staff of the Department of Physics at the Imperial College.

C. C. BUTLER

NEWS and VIEWS

Mastership of Clare College, Cambridge :

Sir Henry Thirkill, C.B.E.

SIR HENRY THIRKILL retires from the mastership of Clare College, Cambridge, on September 30 next. Apart from the war years 1914–19, Sir Henry has been in residence since he entered the College as an undergraduate in 1905. He sat for the Natural Sciences Tripos, Part I, in 1907, and for Part II in the following year. He was elected a Fellow of Clare in 1910, having embarked on research at the Cavendish Laboratory under J. J. Thomson, being later one of his demonstrators in the somewhat precarious days when the professor was personally responsible for his assistant's stipends. During the First World War, Thirkill served in the Royal Engineers, being O.C. Wireless in East Africa, 1915–18, and receiving the Military Cross. On returning to Cambridge, he was appointed College lecturer and a University lecturer in experimental physics. It is, however, as tutor of Clare College from 1920 that he will best be remembered by many generations of Clare men—not only for his gentle if determined guidance but also for his hospitality at breakfast or Sunday evening music and, for the more energetic, on the tennis or squash court. Though made president of the College in 1930, he retained the tutorship until he was elected master in 1939.

Always a great worker, Thirkill found time from an early date to serve the University as well as his College. He was elected a member of the Council of the Senate so far back as 1927, serving continuously for thirty years. This was only a beginning; for many years he was also a member of the General Board of the Faculties, of the Financial Board and of many other committees. It would be difficult to find a man in any age who has given longer or more devoted service in the sometimes thankless task of university administration. Thirkill was vice-chancellor in the particularly busy years 1945–47 when plans for post-war developments were being prepared on every hand. It fell to him to entertain the many war leaders on whom honorary degrees were conferred. His brilliant speeches at the luncheons following the degree congregations will long be remembered. It will be difficult for old Clare men to think of the College without Thirkill as master or tutor, but they may be comforted by the knowledge that he will continue in residence on his retirement.

Sir Eric Ashby

THE Fellows of Clare College have announced their intention of electing Sir Eric Ashby into the mastership of the College on the retirement of Sir Henry Thirkill. Sir Eric, who has been vice-chancellor of The Queen's University, Belfast, since 1950, was elected on March 13 into a Fellowship of the College. From the City of London School, Ashby went to the Imperial College of Science and Technology, where he later became a demonstrator in botany and, after two years in America as a Commonwealth Fellow, a lecturer during 1931–35. His next post was reader in the University of Bristol until 1938, when he was appointed professor of botany in the University of Sydney. The sea-trip to Australia with a young family was so turbulent that Ashby swore never to return. Fortunately for the cause of education in Britain, the busy years that followed made him forget his resolve. Scarcely was he settled in Sydney when the Second World War made heavy demands upon him. He was chairman of the Australian National Research Council, 1940–42, and director of the Scientific Liaison Bureau, 1942–43, having conducted an inquiry for the Prime Minister into the enlistment of scientific resources in 1942. In 1945 he went to Moscow as Counsellor and chargé d'affaires at the Australian legation. His experiences there are recounted in the Penguin book, "Scientist in Russia". In 1946 he left Australia to become Harrison professor of botany and director of the Botanical Laboratories in the University of Manchester, where he remained until he went to Belfast as vice-chancellor. While continuing his interest in botany, Ashby has found time for many other activities, including the administration of research, having been a member of the Advisory Council on Scientific Policy (1950–53), of the Advisory Council on Scientific and Industrial Research since 1954 and chairman of the Scientific Grants Committee since 1955. Above all, he is well known as a writer, and thinker, on educational problems.

Research at Imperial Chemical Industries :

Mr. R. M. Winter

MR. R. M. WINTER, who is retiring from the post of research controller of Imperial Chemical Industries, Ltd., after thirty years service with the Company, was born in Scotland in 1896, and emigrated in early childhood to New Zealand, where he received most of his formal education. On graduating B.Sc. in 1916, he volunteered for military service and served with the New Zealand Division in France, where he was wounded. At the end of the War he worked for a time at the Royal College of Science as a research student under Prof. H. Brereton Baker, and on his return to New Zealand was awarded an 1851 Exhibition science research scholarship. After a year's research at the Rothamsted Experimental Station, he joined the staff of the Explosives Research Department at Woolwich Arsenal, where he remained until the end of 1927. He joined Synthetic Ammonia and Nitrates, Ltd. (now the Billingham Division of Imperial Chemical Industries), early in 1928 and was transferred to the General Chemical Division as research manager in 1931. In 1937 he moved to Head Office as chief assistant to Dr. R. E. Slade, who was then research general manager, and was appointed research controller in 1946.

Dr. M. A. T. Rogers

DR. M. A. T. ROGERS, head of the Academic Relations Department of Imperial Chemical Industries, has been appointed research controller in succession to Mr. R. M. Winter. Dr. Rogers was born at Mill Hill in 1911, and received both the B.Sc. and Ph.D. degrees from University College, London, where he was a Tuffnell Research Scholar and the Ramsey Memorial Medallist for 1933. Dr. Rogers joined the Dyestuffs Division of Imperial Chemical Industries as a chemist in 1934, and served in the Azo Section until 1936, the Textile Auxiliary Section until 1939 and the Exploratory Research Section until 1942. In that year, Dr. Rogers joined the Royal Artillery, and when he returned from his military service he became engaged in research on penicillin with Sir Robert Robinson at the Dyson Perrins Laboratory, Oxford. In 1946, Dr. Rogers joined the Medicinal Research Division, and in 1949 he became head of the Academic Relations Department of the Dyestuffs Division of Imperial Chemical Industries.

Atomic Energy Insurance

THE second international Atomic Energy Insurance Conference, held in London during February 26–28, under the chairmanship of Mr. H. T. Silversides, issued in a widespread agreement by representatives from fifteen European countries on the broad approach to the insurance of risks arising out of the use of nuclear energy reactor installations. Essential features of pool management agreements were discussed, and it was decided that the material damage risks to be pooled should be the insurance of damage to nuclear installations (defined as nuclear reactors, nuclear power stations, and plant and facilities for producing nuclear energy), including contamination by radioactivity. Third party liability for damage and loss of life or injury arising out of the use of nuclear installations is also to be pooled, and each reactor and third party liability must be comprehensively covered. All the participants in the Conference endorsed the principle that a single insurance policy should be effected by the owner or operator of the reactor, who should also accept all responsibility for radiation liabilities for contractors and suppliers of parts, and undertake to indemnify the contractors and suppliers from any legal liability for radiation risks. The Government of the United Kingdom has already agreed to this approach in fixing an absolute liability at law and requiring insurance to a sum of £5 million or proof of equivalent liquid assets. A special committee of representatives of Belgium, France, Germany, Holland, Italy, Sweden, Switzerland and the United Kingdom is meeting in April to consider hazards, evaluations and surveys ; the basis of premium rating ; and the policy cover to be offered ; while legislative aspects of nuclear insurance will continue to be handled by the Organization for European Economic Co-operation and the European Committee for Insurance.

Industry and Atomic Power

AN illustrated brochure entitled "Atomic Power Achievements" (chairman's address at the Fifty-seventh Annual General Meeting, London, September

5, 1957. Pp. 36. London: General Electric Co., Ltd., 1957) describes the part to be played by the General Electric Company, Ltd., in the implementation of the British nuclear power programme. The Company is building at Hunterson on the Ayrshire coast one of the world's largest full-scale commercial nuclear power stations, for use by the South of Scotland Electricity Board. Photographs of models of the station and details of its capacity are given in the brochure. The generating capacity will be 360,000 kW., of which 320,000 kW. will be fed into the National Grid system, the remainder being consumed in the station. The two reactors will be loaded initially with 500 tons of uranium. The graphite core of each reactor will consist of about 115,000 graphite blocks and will be enclosed by a spherical steel pressure-shell 70 ft. in diameter. In addition to the reactors and the turbine hall, housing six turbo-generator sets with feed water and condensing plant, administration and laboratory blocks and a number of ancillary structures will be built. Between the two reactor structures a pond for the storage of irradiated or spent fuel elements from the reactors, prior to their removal to the processing plant, will be constructed. The first reactor and three turbo-generator sets are scheduled for commissioning in 1961 and the whole station will be fully operational in 1962.

Milford Haven Conservancy Bill

On March 25, during the committee stage in the House of Commons of the Milford Haven Conservancy Bill (see *Nature*, April 5, p. 937), the amendments moved by Lords Silkin and Ogmore and others were negatived, although Lord Brecon, for the Government, promised to consider further before the report stage the desirability of placing the provision for amenities in a separate section. Some disturbing disclosures were made during the debate. Lord Ogmore revealed that the Chairman of the Pembrokeshire County Council had opposed the suggestion that the whole scheme for development should first be explained to the nation in a White Paper, and appeared to be concerned solely with local benefits. The Minister of Housing and Local Government had taken a wider view, and had refused the Esso Company permission to develop 1,000 acres, and permission to develop 350 acres had been given only under very stringent conditions. Lord Ogmore pointed out that there were eight developments proposed in the area; besides this proposal for a £20 million refinery on the north shore, there was the landing stage for the harbour at Popton Point capable of taking the largest tankers afloat; a £9 million project for two dry docks, five wet-berths and a discharging pier; a deep-water unloading berth for iron ore; the iron ore stocking ground at Angle or near by; another refinery on or near the Haven; a group of chemical and kindred factories; and a ship-repairing project at Pembroke Dock.

These developments, which it was estimated would bring a further 50,000 people into the area, were likely to have a profound effect on the whole of west Wales and, apart from the effect on the National Park area itself, Lord Ogmore and other speakers were concerned that any essential development should not be allowed to create industrial slums in the way that some nineteenth-century developments had done. His contention that due regard should be had to cultural and social development was strongly supported by Lord Lloyd and by Lord Hurcomb, who welcomed the writing into the Bill of the powers which the Minister of Power agreed to write into the Electricity Bill. Lord Hurcomb was concerned that planning authorities should not be allowed to give free play at the expense of all other considerations to any profitable industrial or commercial development, and referred to the probable deleterious effect of the proposed dredging on the marine biological station at Dale Fort. As regards oil pollution, he thought that much of the evil could be avoided if the responsible authorities were vigilant and exercised their great powers. The oil companies in Britain had always taken an enlightened attitude.

Lord Brecon, in replying to the debate, said that the Government had very carefully considered the amenity question, and thought that the Bill, as it stood, provided all the care for amenity that will be required in the development of Milford Haven. The Minister of Housing and Local Government and for Welsh Affairs had taken great personal interest in the question, and could call in all the planning applications for consideration by his Department. The National Parks Commission would be represented on the Board, which would have greater responsibilities for amenities than any other harbour board in Britain. The Government, he said, is really keen to see that full consideration is given to amenity, and that as little despoliation as possible occurs in the area; but matters of cultural and social development are the responsibility of the local county council, the committee for further education, youth clubs and other organizations.

Entomologia Experimentalis et Applicata

Within a year of the first appearance of the new *Journal of Insect Physiology*, yet another scientific journal dealing with entomology has made its debut. *Entomologia Experimentalis et Applicata* (1, No. 1; February 1958. Pp. 72. Published quarterly. Annual subscription (for a volume of at least 320 pages): 32 Dutch guilders; 63*s.*; 8.50 dollars. Amsterdam: North-Holland Publishing Co., 1958) has a distinguished board of editors drawn from the Netherlands, France, Germany and Great Britain. The first number contains nine papers which formed part of a symposium on "Insect and Foodplant" held at Wageningen in 1957. These interesting papers cover a wide range of topics in insect physiology and biochemistry, ecology, behaviour and plant breeding; but they cannot be regarded as typical of the kind of papers the new journal will carry in the future. The intention is to provide a meeting-ground between experimental and applied entomology. Such problems as the resistance of crop plants to insects, diapause, phenology, biological control and resistance to insecticides are among those which may be expected to figure in future numbers. This journal will certainly serve a most useful purpose. It is well printed and produced on a rather small page measuring 6 in. by 9¼ in.

Worthing Museum

In 1956 work commenced on a complete re-presentation of the collections in the Worthing Museum. During its fifty years history, the Museum's collections have undergone a shift of emphasis from natural history and folk material to archæology, a process which has increased rapidly in momentum in the past decade. This might well have been foreseen, since the South Downs near Worthing have been occupied during every prehistoric period with the exception of the Palæolithic, and the activity of archæologists and archæological societies has brought an increasing yield of displayable material from which a connected and absorbing story can be told. Latterly, too, the Museum staff has undertaken excavations which have made valuable contributions to the prehistory of Worthing. The theme of the new displays, therefore, is the habitation of the South Downs and coastal plain of West Sussex. Small models and diagrams were prepared to assist in the presentation of an easily assimilated visual story, and three more ambitious models and reconstructions were designed to focus attention and hold the interest of the casual visitor. The first of these is a copy of the geological relief map of the Weald in the Geological Museum, South Kensington—the first copy to have been attempted. The second is a large-scale model of a room in the Roman villa at Bignor, originally made for the Festival of Britain Exhibition, and the third is a reconstruction of a Roman cist burial from Avisford, complete with grave furniture. On March 1, Dr. W. E. Swinton, of the British Museum (Natural History), opened the sections already completed, containing material of the periods from Palæolithic to Mediæval times. Cases have already been provided for a new geology bay, and work will commence shortly on a series of period rooms which will continue the sequence down to the nineteenth century.

Gas Chromatography Discussion Group

The Gas Chromatography Discussion Group was formed in association with the Hydrocarbon Research Group of the Institute of Petroleum following the Symposium on Gas Chromatography in London, May 1956, and has the following objects: to promote interest in gas chromatography; to organize meetings devoted to gas chromatography; to compile and distribute gas chromatographic data. The expanding interest shown in the activities of the Group over the past year has necessitated some changes in the present organization. It is proposed to invite interested workers in the field to become members of the Group and to contribute to the planning and execution of its work in the future. The annual subscription will be 1 guinea, which will entitle members to vote at general meetings, attend the informal symposia organized twice yearly and receive such compilations of data or other information as may become available from time to time. The first annual general meeting will be held in London in the autumn of 1958 in conjunction with the next informal symposium. Further information can be obtained from the secretary, D. H. Desty, British Petroleum Co., Ltd., Sunbury-on-Thames, Middlesex.

Geological Society of Australia

The following officers of the Geological Society of Australia have been elected for the year 1957–58: *Vice-President*, Prof. A. R. Alderman (Adelaide); *Vice-President*, Prof. R. T. Prider (Western Australia); *Hon. Secretary*, Dr. N. H. Ludbrook (Department of Mines, Adelaide); *Hon. Treasurer*, Dr. O. A. Jones (Queensland); *Hon. Editor*, Dr. M. F. Glaessner (Adelaide).

The Geological Society of Australia was formally constituted in 1952. Developing originally from informal groups of geologists, it has attained in its sixth year about 470 members and 130 associates. The Society is organized on a Federal and State basis with seven State Divisions. Plenary meetings of the Federal body are held with the meetings of the Australian and New Zealand Association for the Advancement of Science. Until permanent headquarters are established, the headquarters of the Society move after each meeting to the place of the next plenary meeting. The *Journal of the Geological Society of Australia* has been published annually since 1953; Vol. 4, part 2, and two parts of Vol. 5 are due early in 1958. Inquiries regarding subscriptions to the *Journal* should be addressed to the Hon. Treasurer, Dr. O. A. Jones, Department of Geology, University of Queensland, St. Lucia, Brisbane.

A Cytotaxonomic Study of *Carex*

Áskell and Doris Löve and Marcel Raymond have given a cytotaxonomic account of the *Capillares* section of *Carex* (*Canadian J. Bot.*, 35, 715; 1957). This section comprises nine distinct species, one of which (*C. boecheriana*) is raised to specific status in this paper. Three species include two distinct subspecies each; two varieties and three formæ are accepted for two species, respectively. The chromosome numbers of the taxa involved are $2n = 18$, 36, 38, 40, 54, 56 and 58. The authors point out that the chromosomes of *Carex* have a polycentric or diffuse kinetochore and that this explains the aneuploid variations in number known to be typical of the genus. Karyotypic analysis of the chromosome complements of the section *Capillares* revealed that in the basic diploid set of $2n = 18$ chromosomes, four units are long, ten are medium and about half the length of the long ones, while four are small and about half the length of the medium ones. This frequency of size classes is also met with in the plants with $2n = 36$ and 54 chromosomes. Those taxa with $2n = 38$, 40, 56 and 58 chromosomes show, however, such a deviation in the frequency of the size classes that it seems logical that these numbers have been produced by a secondary fragmentation of the chromosomes. On the basis of karyotypic analysis of this section and other groups of the genus, it is concluded that the primary basic number for the genus *Carex* in particular, and the family Cyperaceae in general, must have been $x = 5$, all other numbers having been derived mainly by fragmentation of chromosomes with a polycentric or diffuse kinetochore. This phenomenon of partial agmatoploidy is widespread in Cyperaceae, whereas complete agmatoploidy is typical of the closely related Juncaceae.

Spectrophotometric Study of Stars with High Velocities

Madeleine Chopinet has a paper with the title "Étude spectrophotométrique de quelques étoiles à grande vitesse", in *Publications de l'observatoire de Haute Provence* (3, No. 42; 1957), which analyses a number of spectra of stars taken with the 120-cm. Newtonian telescope at Haute Provence. The dispersion of this spectrograph with a flint prism was, unfortunately, rather low—about 50 A./mm. towards 3900 A. and 80 A./mm. towards 4400 A. All the photographs contained certain stars which were to be studied, together with several comparison stars. The deductions confirm the results of several other investigators, particularly of Keenan and Keller (*Astrophys. J.*, 117, 241; 1953). In the opinion of the author, however, they are not sufficiently characteristic to serve as criteria for stars with high velocities. She has searched the records of high-velocity stars the trigonometrical parallaxes of which are known; about 2,200 are given in Miczaika's list (*Astro. Nach.*, 270, 249; 1940) and fifty others elsewhere. The Russell diagram for these stars is compared to the diagram for about 650 normal stars in the vicinity of the Sun, for spectral types between $F0$ and $M5$. It appears that the branch corresponding to the main sequence for stars of high velocity is nearly 0·5 magnitude below that of the normal stars. The number of giants of both categories is too small to draw any conclusions about them.

1958 Waverley Gold Medal Essay Competition

The Waverley Gold Medal and £100 will be awarded for the best essay of about 3,000 words based on some recent scientific research or new development (whether the author's work or not), giving some indication of the scientific background, the experimental results and its potential application in industry. The essay should be written in a form that is clearly intelligible to a scientist engaged in another field or a director of an industrial firm. The essays will be judged for technical content by specialists in that field, for clarity of presentation and style. A second prize of £50 will also be awarded, and an additional prize, also of £50, for the best entry from a competitor under thirty years of age on July 31, 1958. The competition is open only to persons at present engaged in scientific work. Further information can be obtained from the Editor, *Research*, 4/5 Bell Yard, London, W.C.2. All entries must be received on or before July 31.

"Natural Gas in Scotland"

Referring to the article under this title in *Nature* of December 28, p. 1444, Mr. T. S. Ricketts writes: "The British Petroleum Co., Ltd., has pointed out that the Cousland anticline was not discovered by the D'Arcy Exploration Co., Ltd., but is a well-known feature of the geological maps published by H.M. Geological Survey and has been known for a very long time. It was first tested shortly after the First World War, when a small amount of gas was proved. Most of the present sub-surface knowledge of the Cousland anticline was obtained by test drillings by the D'Arcy Exploration Co. and the Anglo-American Oil Co. during the period 1937–39. It was at this time that the gas accumulation now being used by the Scottish Gas Board was discovered by the D'Arcy Exploration Co. The local crest maximum with the natural gas in it may have an east-to-west long axis, but the anticline runs north and south and not east and west".

University News: Belfast

The following appointments to supernumerary lectureships have recently been made in The Queen's University of Belfast: R. H. Buchanan (geography); J. F. Gracey and W. A. M. Gordon (veterinary science); J. Patton (agricultural bacteriology); Dr. C. E. Wright (plant genetics and plant breeding); Dr. A. M. Raven (agricultural chemistry); and Dr. A. G. Smith (botany). Dr. J. L. Douce has been appointed lecturer in electrical engineering.

London

Dr. Leslie Crombie, lecturer in organic chemistry at the Imperial College of Science and Technology, has been appointed to the University readership in organic chemistry tenable at King's College.

Announcements

The National Institute of Industrial Psychology has appointed Mr. J. D. Handyside to the post of controller of research, with effect from April 1.

Dr. Ethelwynn Trewavas has been appointed a deputy keeper in the Department of Zoology, British Museum (Natural History). She has been a member of the scientific staff of the Museum since 1935 and is a leading taxonomic ichthyologist, her special study being freshwater fishes.

Mr. J. D. Alston, a well-known Norfolk farmer, has been appointed a member of the Agricultural Research Council, to fill a vacancy on the Council. Mr. David Lowe, a member of the Council since 1954, has been appointed deputy chairman in succession to Prof. S. J. Watson; Prof. Watson will continue to serve as a member of the Council and as chairman of the Council's Standing Committee on Research affecting Plants and Soils.

The Physical Society is holding a conference on "Spectroscopy of Solids" at the Royal Radar Establishment, Malvern, on May 28 and 29. Further information can be obtained from the Secretary, Physical Society, 1 Lowther Gardens, Prince Consort Road, London, S.W.7.

The eleventh Brookhaven symposium in biology will be on "The Photochemical Apparatus: its Structure and Function". It is sponsored by the Biology Department, Brookhaven National Laboratory, Associated Universities, Inc., Upton, New York, and will be held during June 16–18. Further information can be obtained from Dr. R. C. Fuller at the above address.

The seventeenth meeting of the European Federation of Chemical Engineering will be a joint symposium on "The Organization of Chemical Engineering Projects". It will be held at Olympia, London, during June 24–26. Further information can be obtained from the Institution of Chemical Engineers, 16 Belgrave Square, London, S.W.1.

A symposium on "Continuous Cultivation of Micro-organisms", sponsored by the Institute of Biology of the Czechoslovak Academy of Sciences, will be held during June 23–28 in Prague. The symposium will deal with some theoretical aspects of continuous cultivation and the possibilities of the practical applications of this method. Further information can be obtained from Academician I. Málek, Institute of Biology, Czechoslovak Academy of Sciences, Na cvičišti 2, Praha 6, Czechoslovakia.

Dundee Technical College offers two one-week special summer programmes to bring information on electronic data processing methods and developments to those who are or may be involved in selecting, programming, operating or managing electronic computers. These are "Electronic Computers and Business Problems", to be held during June 23–27, and "Developments in Electronic Data Processing for Business", to be held during June 30–July 4. Both programmes will be directly supervised by Dr. Robert H. Gregory, professor of accounting, Massachusetts Institute of Technology, assisted by Dr. Stanley Gill, head of the Computing Research Group, Ferranti, Ltd., England. Further information can be obtained from the Head of the Department of Management Studies, Dundee Technical College, 40 Bell Street, Dundee.

University College of Science PHYSICS Dept. 92, Upper Circular Rd., Calcutta.

HEALTH AND SAFETY IN THE ATOMIC ENERGY AUTHORITY

THE report of the Committee appointed under the chairmanship of Sir Alexander Fleck to review the organization of the Atomic Energy Authority as a whole for the control of health and safety[*] begins by describing the measures which the Committee considers essential. Safe technological practice, it believes, involves: (*a*) formulating codes of practice for design and operation based on experimental facts and experience; the special problems of nuclear energy require that preparation of the codes should be the responsibility of specialist health and safety staff; (*b*) designing plant using these codes of practice; this is the responsibility of design engineers; (*c*) operating and maintaining the plant to these codes; the executive responsibility for this rests with the works general manager and his operating staff; (*d*) overall monitoring of both design and operations by the safety staff, whose duty it is to direct the attention of the executive authority to any lapse from the prescribed codes.

The report next considers the functions of Government departments in this field and, after defining the Authority's role in relation to health and safety measures, the Authority's organization against this background. The national implications of the acute shortage of specialist health and safety staff in the field of nuclear energy to which the report directs attention, and the recommendations of the Committee in this connexion, and in regard to the Authority's external relations and responsibilities, are discussed elsewhere (p. 1023 of this issue). The internal recommendations are summarized below.

The Fleck Committee endorses the Authority's decision to establish a committee of the Atomic Energy Executive to be responsible for the overall supervision of all matters of health and safety, but recommends some minor changes in the terms of reference. It considers that the new committee structure established under the Executive Committee on Health and Safety provides an effective means of controlling health and safety throughout the Authority. Recommended terms of reference for the subordinate Weapons Safety Executive Committee, Safety Executive Committee and Health Executive Committee are suggested. It also recommends that the management of health and safety in the factories of the Industrial Group should be fully integrated into a single section responsible directly to the works general manager and endorses the new health and safety organization at Risley and the concept of an Authority Safety Branch which it contains. This organization, it is suggested, should be brought up to strength as a matter of urgency, and detailed terms of reference for the Industrial Group Health and Safety Branch are suggested covering the preparation of codes of practice, and provision of a medical service, radiological safety service and industrial safety service at each site, and provision of an independent inspection service.

The Committee recommends that there should be one senior member of the scientific staff at the Radiochemical Centre, whose principal duty would be functional responsibility to the manager for all safety matters. Existing members of the staff should be given this duty on a rota basis, and a first task of the new safety officer should be to investigate storage arrangements for radioactive materials. It is also recommended that the Authority should bring the site emergency procedures in each of its establishments to a uniformly high standard. The procedures should be co-ordinated to ensure that the maximum technical resources of the whole Authority may be deployed to counter an emergency in any single establishment. Finally, there should be closer collaboration between the Authority's three Groups on the problems concerned with the control of criticality, and each Group should have a nominated officer to bear functional responsibility for criticality problems.

INDUSTRIAL HEALTH IN GREAT BRITAIN

THE annual report[*] of the Chief Inspector of Factories for 1956 records a reduction of 2 per cent in the number of accidents, from 163,332 in 1955 to 160,116, although the estimated number employed in factories increased by 0·4 per cent. The downward trend in the accident rate per thousand employed continued, as did the fatality rate per million employed (54), the number of fatal accidents in factories being 426; and of 184,785 accidents notified during the year from all premises subject to the Factories Acts, 687 were fatal. The Chief Inspector observes that probably greater efforts have never been made than during the past year to reduce the risk of accidents due to fire; and these efforts, which are part of a continuing campaign carried out by the inspectorate, other Ministries, local authorities, fire services and various organizations, have been intensified, and co-operation between the authorities and services has been strengthened and extended.

The cardinal importance of the contribution of the scientist and technologist to health and safety in industry is again apparent from this report. Thus, reviewing progress on safety, the report stresses four aspects, in all of which that contribution is decisive. First, the need to design for safety. Secondly, the tendency for electrical and electronic apparatus to be included where formerly reliance was placed only on a mechanical system of control. Thirdly, and in consequence, greater reliability is required of such apparatus to ensure the safety of operators, since failure may lead to unexpected and dangerous movement. Accordingly, extensive studies are being undertaken of the reliability of complex electrical and electronic equipment, and there is every expectation that, in future, fault-finding will be made to some extent automatic, so that the production process may be kept going with a minimum of costly interruption. Fourthly, the problems of safety in the nuclear power stations are briefly reviewed (see p. 1023 of this issue).

---

[*] Ministry of Labour and National Service. Annual Report of the Chief Inspector of Factories for the year 1956. Pp. 195. (Cmnd. 329.) (London: H.M. Stationery Office, 1958.) 9*s*. 6*d*. net.

There has been steady improvement in all fields of safety, and the Chief Inspector believes that accident prevention is gaining momentum, but that we need to set our sights a good deal higher. In referring to training in safety, he expresses the hope that the technical colleges will take greater interest, and that in the expanded programmes a place will be found for spreading the fundamental principles of safe working. The Clean Air Act, where it reduces the pollution of the atmosphere, has immediate repercussions on standards of cleanliness and lighting, and the Food Hygiene Regulations, 1955, have stimulated both food-products factories and factory canteens to further effort in cleanliness, both general and personal. Work continued on the surveys initiated by the Industrial Health Advisory Committee into conditions affecting health, and that on the Halifax Survey was practically completed during the year.

At the end of 1956, some 362 factories, including five receiving depleted uranium oxide from the Industrial Group of the Atomic Energy Authority at Risley, were receiving radioisotopes from Harwell and the Radiochemical Centre, Amersham, compared with 300 at the end of 1955, the most extensive use being for γ-radiography of castings, welds, etc., chiefly with iridium-192 and cobalt-60, though cæsium-137 continues to gain in favour. A draft code of regulations for the use of radioactive materials (other than for luminizing) was examined by an expert committee, and as a result draft regulations in respect of sealed sources were nearly complete by the end of the year and have since been published. The Radiological Protection Service made a concerted drive, with the Factory Inspectorate, to improve still further the protection of radium luminizers. The use of radioactive material for the elimination of static electrical charges continues to increase slowly.

SCIENTIFIC AND TECHNICAL TRANSLATION

A CONFERENCE on "Scientific and Technical Translation", organized by Aslib, was held at the Connaught Rooms, London, W.C.2, on March 5. Dr. J. E. Holmstrom of Unesco and Mr. E. B. Uvarov were chairmen for the morning and afternoon sessions respectively and about two hundred visitors attended. Mr. L. Wilson (director of Aslib) and Dr. Holmstrom introduced the subject, indicating that it had been examined in a report by Unesco* and was of increasing importance in facilitating scientific communication. Even if the problem were restricted to that experienced by those speaking English, it was found that about half of the world literature was unintelligible without translation. For those with other mother tongues the difficulties were far worse. The Unesco report contains the bulk of the factual information now available on translating methods, services, costs and indexes.

Three papers were presented: "The Organization and Availability of Technical Translation", by Dr. A. L. Mackay (Birkbeck College, London); "The Economics of Translation", by Mr. Felix Liebesny (Mond Nickel Company); and "Training for Translating Work", by Mr. A. G. Readett (National Coal Board, vice-chairman of the Institute of Linguists).

Dr. Mackay surveyed possible and actual methods of organizing the extraction of information from foreign-language literature, translation being regarded as an unproductive activity to be avoided if possible. The inefficiency of making a translation for one person who found only a fraction of it informative could be mitigated by circulating translations widely, regular cover-to-cover translations of major periodicals being the most systematic way of sharing expenses. Indexes of individual translations were thought to be only marginally useful. Persons properly qualified for scientific translation work would be better employed as full members of research and development groups working with linguistic and library rather than, say, chemical techniques. Material for translation should be selected for its value, reviews, digests and books being preferred; and an estimate of the premium to be placed on rapid processing could be made by attaching half-lives to various categories of literature. Training students in languages and maintaining scientific representatives abroad could reduce the volume of translation necessary.

Mr. Liebesny examined the actual costs, to an organization using translations, of various methods of preparation. He found that, where a complete text was required, the cost of translating a 1,000-word article from Russian to English was about 50*s.* to 120*s.*, depending on particular techniques (use of recorder, typist, etc.) and salary rates. If the translator worked through the paper orally with the inquirer, translating only part, the cost could be reduced to 17*s.* to 28*s.* Mechanical translation, according to the most optimistic forecasts, might cost 2*s.* per thousand words. Under various co-operative schemes, such as that run by the Department of Scientific and Industrial Research, where the costs are shared, the charges might vary from 8*s.* to 30*s.* For cover-to-cover translations of periodicals the cost would be only 4*d.* to 6*d.*, so that even assuming that only 2½ per cent of the papers which had to be bought were actually required and worth translating, the cost per thousand words would still be only 13*s.* to 20*s.* For such co-operative translations the choice of material is not wholly under the inquirer's control and certain papers would still have to be dealt with individually.

Mr. Readett described how translators at the London office of the National Coal Board were trained to prepare abstracts, to make full translations and to provide interpreter services. Only professional linguists of honours degree standard were recruited and they were familiarized with the technology of the subject. The close and harmonious relations maintained with the Board's technicians were especially emphasized. Visits, lectures and films, such as instructional films on new machinery, were used in addition to background reading material to ensure that translators were familiar with the subjects of the papers they had to translate. Only the highest quality of written translation was produced but, for speed, when only one inquirer wished for a translation, the paper could be very satisfactorily examined orally by the translator and the subject specialist. The concept of a 'rough translation' as something cheaper and easier to make than proper translation was based on a misunderstanding of the translation process which was to understand first, and then to re-express in English. Many papers could be clearer in a well-expressed translation, but those papers which were obscure, because they were ill-written and ambiguous even to a specialist, imposed an intolerable burden on the translator.

---

* "Scientific and Technical Translating and Other Aspects of the Language Problem", Unesco, 1957; second edition, 1958. (H.M. Stationery Office.) 20*s.*

In discussion, Dr. D. J. Urquhart (Department of Scientific and Industrial Research) supported an organized system of cover-to-cover translation as the only real answer to the situation, together with the widest possible use of English by scientific journals. There was general agreement with this and with the proposition that students should be trained in foreign languages, particularly Russian, if only to employ translators more effectively. It was recommended that those translating papers should notify the Aslib index when they begin a translation so that duplication might be avoided. Many enthusiasts spoke on various aspects of translation without expressing views which diverged seriously from those of the main speakers, except that many preferred that scientists should be trained in languages rather than that linguists should be taught technology.

It was resolved, on the initiative of Dr. Urquhart, that Aslib should be recommended to convene a further conference "to see what measures can be taken to make Russian scientific and technical literature available in English". The meeting also passed a resolution from Dr. Clason (Philips, Eindhoven) that the whole question of translation required fuller consideration by a three-day conference. Discussion was terminated with a resolution that the Unesco Report proposals, circulated with the conference documents, should be sent out to participants as a questionnaire, so that the opportunity of obtaining the opinions of those attending the conference should not be lost through lack of time. The papers and discussion will be published later in "Aslib Proceedings".

A. L. MACKAY

HIGH POLYMERS

THE Kelvin Lecture, delivered on February 6 to the Institution of Electrical Engineers by Sir Harry Melville, dealt with the chemical structure and physical behaviour of high polymers. After giving an account of the underlying principles, Sir Harry dealt with natural and artificial rubber, polyethylene, synthetic fibres and ion-exchange fibres. The lecture brought out very well the co-ordination of chemistry, physics and engineering in the field of high polymers, and showed to what a large extent materials of this kind are finding all kinds of uses, and how their properties may to some extent be controlled on the basis of theory.

The fundamental property of a high polymeric material is its high molecular weight, which may increase from upwards of 10,000 to values of the order of a million for linear molecules and indefinitely large values for non-linear systems. The molecules should consist of long chains of atoms to which side-chains are attached. The groups in these side-chains may be able to rotate freely or may be joined by cross-links. If the main chain contains double bonds, its members will be hindered from rotation. If the number of molecules in the chain is not very large, the chain may coil into a spherical shape, and rubber is normally in this form. In stretching the rubber, the chains uncoil under moderate tension. Unvulcanized rubber behaves differently and tends to crystallize on extension. Vulcanization puts in cross-links, which are not extensive enough to prevent uncoiling. In synthetic rubbers the aim is to produce chains not long enough to form crystallites, and a recent discovery by the British Rubber Producers Research Association consists in modifying the chemical composition so that the chains cannot form such crystallites.

Silicones have chains of silicon and oxygen atoms in repeating units with various groups attached to the silicon atoms. They vary from mobile liquids, the viscosity of which is only very little affected by temperature, to rubber-like solids.

Polyethylene is a linear chain of carbon atoms with hydrogen atoms attached when the polymerization is carried out at room temperature. At higher temperatures and high pressures the molecules have many branches attached to the linear chain, and this has an important effect on the properties. By exposure to high-energy radiation such as gamma-radiation, hydrogen atoms are removed from the chains, leaving free radicals, which join to give cross-links, forming a three-dimensional structure which at high enough temperatures decomposes rather than melts.

Synthetic fibres must have a high tensile strength. It is curious that among the strongest natural and synthetic fibres the tensile strength does not vary much. The strength is much less than that calculated for breaking the chemical bonds, and it is less than the calculated value for other plausible structures, so that no explanation is yet known. The modulus of elasticity is close to the calculated value. The lecture dealt with the changes produced by altering the chemical composition. Fibres and rubber are closely related and relatively small changes in chemical structure influence their properties quite markedly.

Ion-exchange fibres are made by mixing high-polymer molecules containing carboxyl or acid groups and hydroxyl or alcohol groups, and heat treatment. They are in effect solid acids. In an acid liquid the fibre swells. If the acid is replaced by an alkali the molecules stretch, but if the fibre is put into acid its original state is restored. Theoretically, mechanical energy could be derived from such a system, but at present the efficiency is very low.

NEW INSTALLATIONS FOR B.B.C. TELEVISION

SINCE June 1955 a series of Engineering Monographs* has been published by the B.B.C., dealing with technical subjects within the field of television and sound broadcasting. Each Monograph describes work carried out by the Engineering Division of the Corporation and includes, where appropriate, a survey of earlier work on the same subject. About six Monographs are produced each year.

Monograph No. 12 is entitled "An Improved 'Roving Eye'", by T. Worswick and G. W. H. Larkby, and it describes the new design of mobile television camera which, with its associated equipment and short-range radio-link transmitter, permits pictures and their sound accompaniment to be broadcast while the vehicle is in motion and unimpeded by any connecting cables. The vehicle is equipped with two cameras, one of which gets a direct view forward through the windscreen or at right-angles to take kerbside interview shots. The second camera is mounted on a machine-gun ring and can be elevated with its operator to a position well clear of the roof. With this arrangement the camera can be swung to look all around the vehicle; and it can also be tilted on the mounting to take steep downward shots, for example to look on the pavement or in shop windows. The sound and vision signals are transmitted to the broadcasting network by a radio link on a frequency of about 660 Mc./s. When the vehicle is 'roving', a short aerial a few feet high is used to enable the van to pass under bridges; and in this case the maximum distance from the receiving base is some two or three miles. The vehicle is, however, also provided with a 45-ft. pneumatically operated telescopic mast, which can be used from a fixed position to send the signals over a distance of ten to fifteen miles from the receiving base. The normal crew of the vehicle comprises a driver, two cameramen, two operators, a commentator and producer; and the equipment is complete with an engine-driven alternator for the power required by the cameras, control units and the radio transmitter.

The two succeeding Monographs describe the premises at Hammersmith which the B.B.C. has recently converted into a self-contained television studio centre. No. 13 is entitled: "The B.B.C. Riverside Television Studios: The Architectural Aspects", by E. A. Fowler. It describes in some detail, with appropriate drawings and photographs, the planning and construction of the two studios, occupying 6,000 and 4,200 sq. ft., respectively, together with all the necessary equipment and facilities for the staging and production of television programmes. The incorporation of many new features on the engineering side, particularly in the fields of lighting control and co-ordination of the production and engineering staffs, has been made possible by the careful planning and layout of the studios and their auxiliary areas.

The technical accommodation and equipment are described in more detail in Monograph No. 14, entitled: "The B.B.C. Riverside Television Studios: Some Aspects of Technical Planning and Equipment", by H. C. Nickels and D. M. B. Grubb. As in the former case this number is well illustrated with plans, diagrams, photographs showing the studios, control rooms and associated lighting, camera and telecine equipment. The Riverside Studios represent the latest and most modern practice in the equipment of television studios in Britain: while they include certain novel features, they are essentially the outcome of experience gained over a considerable number of years.

THE PHYSICAL SOCIETY DURING 1957

THE 1957 Year Book of the Physical Society (pp. iv+132. London: The Physical Society, 1957. 12s. 6d.) is the third in the annual series and contains the report of the Council of the Society for 1956; the proceedings of the meetings of the Society; obituary notices of five fellows, including Sir Francis Simon and Sir John Townsend; and the texts of the presidential address and of the special lectures and discourses delivered to the Society during the year.

The presidential address, entitled "The Physics and Chemistry of Metals", was delivered by Prof. N. F. Mott on June 4, following the annual general meeting of the Society (see *Nature*, **180**, 272; 1957). The forty-first Guthrie Lecture, given by Prof. H. C. Urey on April 9 during the spring meeting of the Society at the University of Nottingham, was originally entitled "Some Chemical Limitations on Theories for the Origin of the Solar System". However, Prof. Urey has since been able to study the interesting observations of E. K. Gerling and L. K. Levskii made in 1956 in the U.S.S.R. and he has consequently modified and added many points and details to his lecture, with the result that the revised text appears under the title "Meteorites and the Origin of the Solar System". Prof. Urey points out that though meteorites have been investigated by chemists and mineralogists for more than a century, since the Second World War new and modern techniques have been applied to the problem, and he proceeds to review both the older and more recent data, and to outline possible series of events which may have led to the formation of meteorites. Recent work on radioactive dating methods, it is stated, shows conclusively that a most involved series of chemical and physical processes took place some 4·5 aeons ago (an aeon is 10^9 years) during the period in which the solar system originated.

In the nineteenth Thomas Young Oration which he delivered on May 15, Dr. J. Guild, of the National Physical Laboratory, describes observations on the behaviour of diffraction gratings, dealing particularly with those properties which affect image formation. Following a description of the test-bench employed at the Laboratory for the examination of the gratings, a number of examples are given of the peculiarities of behaviour of typical diffraction gratings of various origins as revealed by the tests. The examples show that the best gratings, regarded as optical instruments, are of poor quality by the standards normally applied to plane or concave reflectors, thus leaving considerable room for improvement in the technique of their production.

The magnetic refrigerator for temperatures below 1° K. was the subject of the thirty-third Duddell Medal address given by Prof. J. G. Daunt. A shortened version of the address (for the full text see *Proc. Phys. Soc.*, B, **70**, 641 ; 1957) is included in the Year Book, together with the thirty-fourth Duddell Medal address on the scale-of-two counter by Dr. C. E. Wynn-Williams ; the twelfth Charles Vernon Boys Prize address on "Hyperons and *K*-mesons : a Survey of the Results of the First Decade" by Prof. G. D. Rochester and Dr. C. C. Butler ; the thirteenth Charles Vernon Boys Prize address by Dr. L. Essen on the measurement of the velocity of light ; and the three evening discourses delivered at the forty-first Physical Society exhibition of scientific instruments and apparatus during March 25–28.

PUBLIC HEALTH TRAINING OF GENERAL PRACTITIONERS

In many countries, general practitioners are required, in addition to their private practice, to devote part of their time to public health activities. They are thus called upon to play an important part in the protection of public health—a role for which they have not always received adequate training. A conference* to discuss this problem was organized by the World Health Organization in October and ovember 1956.

NThe main tasks of the conference were to examine the reasons for the frequent indifference of general practitioners to public health questions, to seek a means of arousing their interest in them, and to establish certain general principles for the guidance of those responsible for the organization of the public health training of general practitioners.

It was agreed that the first cause of indifference is in the present university and post-university curricula, which lay the main emphasis on diagnostic and therapeutic aspects. This is a gap which has to be bridged if the general practitioner is to be able to fulfil his public health role efficiently. Another reason for the lack of interest is that the young medical graduate finds the prestige and material compensations of private practice more attractive than public health work.

If the general practitioner's interest in public health work is to be aroused, the health authorities have to keep him informed of their plans for collective activities, and—whenever possible—invite his participation. For his part, the practitioner should realize that, even from the point of view of individual therapeutic care, there are advantages in having a modern public health service at his disposal.

There are various ways of maintaining effective liaison between the health administration and general practitioners, including periodic health bulletins, personal contacts and organization of meetings. Courses and seminars in which general practitioners are invited to participate are particularly helpful, and in several countries excellent results have been obtained by international teaching teams which have organized lectures and discussions in hospital centres on public health.

The report examines in detail the organization of courses for part-time public health medical officers and the various related problems, including time and place of courses, selection of teachers, content and arrangement of syllabuses. If physicians are to become familiar with the nature and aims of public health activities, if they are to take as much interest in these as in other aspects of their profession, and if they are to acquire the necessary technical competence, training programmes should cover, among others, the following subjects : role of the physician in society ; role of the public health administration ; reciprocal collaboration ; epidemiological methods ; environmental sanitation ; importance of external services (social services) ; and the interrelationship of curative and preventive medicine.

SENSORY DEPRIVATION AND THE CAT'S OPTIC NERVOUS SYSTEM

By Dr. LAWRENCE WEISKRANTZ
Psychological Laboratory, University of Cambridge

That rearing in darkness of rabbits[1], cats[2] and chimpanzees[3] can produce severe behavioural impairment in visual tasks is now well established. Less certain is whether this impairment can be attributed to peripheral neural changes, to the lack of opportunity to learn how to see—reflected, presumably, in neural changes limited to more central loci—or to both these factors.

The present investigation was undertaken to examine carefully the visual system of cats reared in darkness. The rearing was intentionally designed to conform to the schedule of an earlier study by Riesen, Kurke and Mellinger[2]. The five experimental animals were put into a dark room from the age of 7 days (before their eyes were opened) until they were 17 weeks old. From their fourteenth to seventeenth weeks, they were given a daily ½-hr. run in a normally illuminated room. During this period, the left eye of each animal received only diffuse illumination. This was achieved by fitting the animal with a mask with a semi-translucent insert in front of the left eye. The right eye received normal unobstructed stimulation. Riesen, Kurke and Mellinger found that cats reared in this manner not only had difficulty in

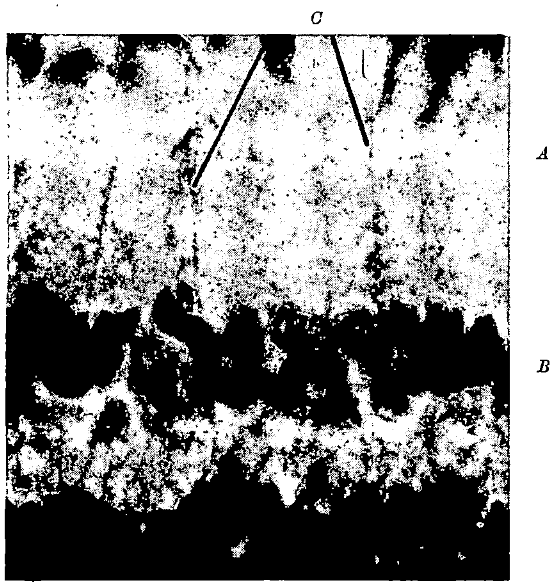

Fig. 1. Photomicrograph of the retina of a cat. *A*, inner plexiform layer; *B*, inner nuclear layer; *C*, Müller fibres. (× *c*. 450)

learning pattern discriminations with either eye, but had a deficit in transferring habits learned with one eye to the other eye. I observed, similarly, that the cats were severely impaired in discriminating objects and depth during their runs, although since my animals were killed at the end of the 17-week period there was not time to carry out the extended behavioural procedures which would be required for a complete replication of the earlier study, particularly those aspects concerned with interocular transfer.

The five experimental kittens were litter mates. As it was not practically possible to have matched or litter-mate controls, an attempt was made to obtain a fairly wide range of ages of control animals. At the time of death these ages were 10, 13, 18, 18 and 75 weeks (the last being the mother of the experimental kittens). The control cats were kept in well-lit laboratory rooms in cages identical to those of the experimental animals. The experimental kittens were 17 weeks old at the time of death.

All animals were killed with coal gas, and the eyes and optic nerves fixed in Bouin's solution. The brains were fixed in formol. The eyes and nerves were eventually embedded in 'Celloidin', the brains in paraffin. A variety of staining procedures were employed.

In microscopic examination of the retinas, no differences between controls and experimental animals were immediately obvious. After considerable examination, however, the impression was gained that there were some differences of a statistical or relative nature rather than all-or-none. In particular, experimental retinas seemed to have fewer clearly stained fibres transversing the inner plexiform layer, particularly Müller fibres. In addition, the inner plexiform layer appeared to be relatively thinner in the experimental retinas. Measures of these two features, therefore, were obtained. Molybdic acid hæmatoxylin was found to be the most suitable stain for both purposes. The sections were 10μ thick.

Before measuring the thickness of the inner plexiform layer, the slides were coded by an assistant so that it was not evident which was control and which experimental. Four specified points on each of two slides for each of the twenty eyes were used. The slides were chosen at random, the only restriction being that the sections had to be cut through the blind spot. The thickness of the over-all retina, the inner plexiform layer, and the inner nuclear layer was measured under high-power oil immersion (Fig. 1). Upon decoding and averaging, the distribution shown in Fig. 2 was obtained. The inner plexiform layers in the experimental eyes were thinner than those in controls. This was true both in absolute terms and in terms of the thickness relative to the over-all retina. The latter was about a 15 per cent difference, on the average, and was significant at the 1 per cent level by the Mann–Whitney non-parametric test[4]. There was some tendency for the retinas of control animals to be thicker over-all than those of experimental animals (Fig. 3); but this was not marked nor statistically significant. There was no suggestion of a difference in the relative thickness of the inner nuclear layer (Fig. 4). These measurements were repeated by another member of the laboratory, with comparable results.

Müller fibres were counted in two sections of each retina, the only condition being, again, that the sections had to include the blind spot. Under oil immersion, every recognizable fibre which travelled at least half the distance from the ganglionic layer through the inner plexiform layer was counted. The sections were not coded. The fibre counts were converted into density measures (fibres per unit length) since there was considerable variation in the actual retinal perimeters. The results are shown in Fig. 5. The experimental retinas are about 20 per cent less dense in the populations of Müller fibres than the controls. This difference is also significant at the 1 per cent level by the Mann–Whitney test. (Actually, 'Müller fibres' is certainly too broad a designation, since the count included a variety of fibre types. However, Müller fibres—so far as it is possible to identify them on the basis of the usual descriptions of them—certainly dominated.)

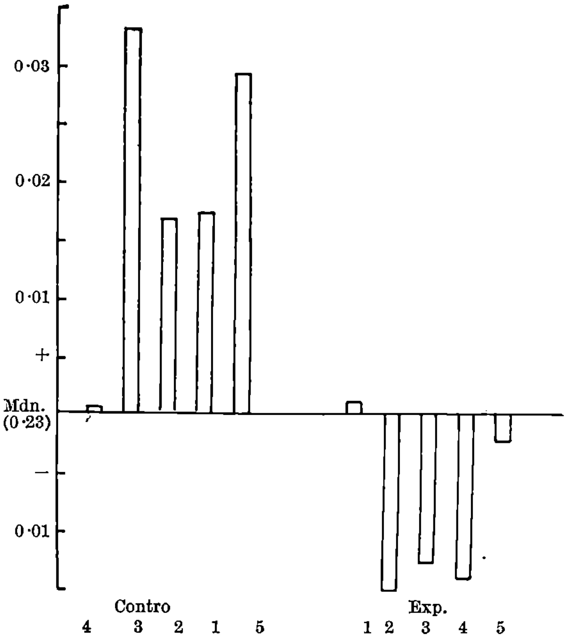

Fig. 2. Relative thickness of inner plexiform layer

No significant difference between the right and left retinas of the experimental animals could be found in the above measures. No differences in the size or distribution of ganglion cells appeared between groups or between left and right experimental eyes.

Finally, density measurements were obtained of fibres in the optic tract. Glees silver stain was used, with control and experimental brains embedded in the same block, sectioned and stained together. This was done as control, for variation is often characteristic of silver stain. Each tract on each side of each brain was sampled at twelve designated positions and fibres crossing a particular grid line under high-power magnification were counted. Experimental tracts were compared only with the corresponding control tracts on the same section. Out of nine such comparisons (one comparison was impossible to make because of poor staining), control tracts were more dense than experimentals in eight cases. Such a difference is significant at the 5 per cent level by simple binomial analysis. The amount of the difference was small, averaging about 6 per cent.

Chow, Riesen and Newell[5] have recently published a study of retinal changes produced by rearing chimpanzees in the dark. They found almost complete disappearance of ganglion cells in the case of two animals kept in darkness for $1\frac{1}{4}$ and $2\frac{1}{2}$ years. A 'normal' retina was found for a third chimpanzee reared in the dark for 7 months, with limited daily experience of non-patterned stimulation, and which was afterwards brought out into the light for two years. But these investigators do not report any control material, and give no basis for assuming that this third retina was in fact entirely normal. Nor is it known, of course, whether it was not more obviously abnormal when the animal was first brought out into the light.

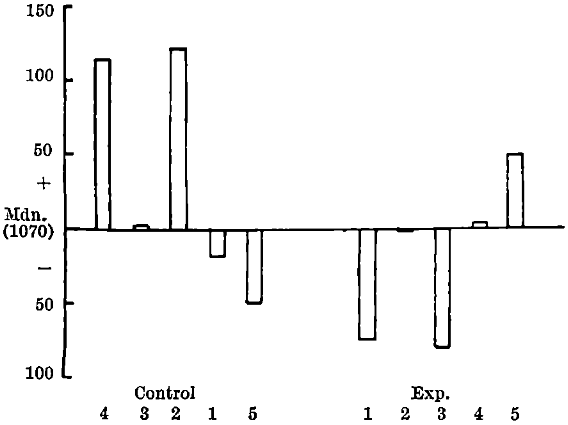

Fig. 3. Relative thickness of retina

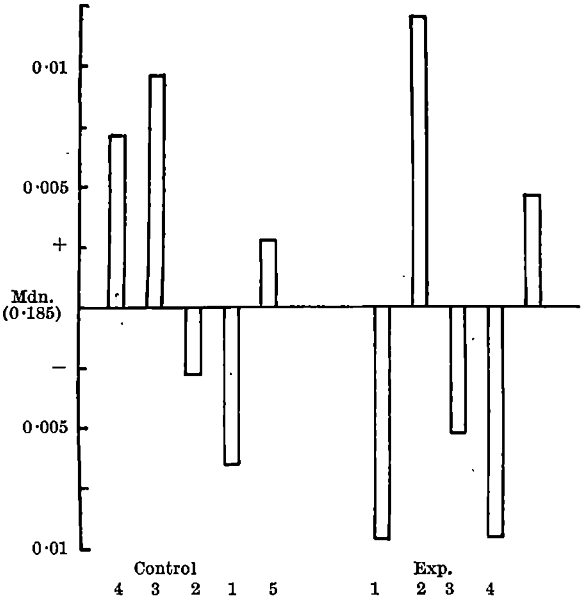

Fig. 4. Relative thickness of inner nuclear layer

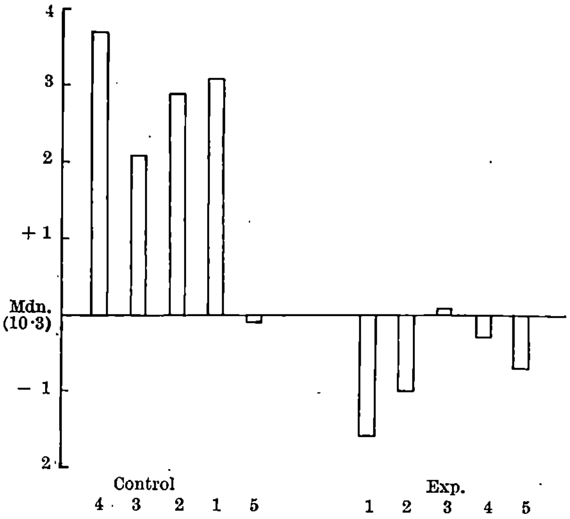

Fig. 5. Density of Müller fibres

Brattgård[6] has reported an elegant study of the pentose nucleoprotein fraction of retinal ganglion cells of rabbits reared in darkness. It was found that 10 weeks of darkness from birth yielded a pentose nucleoprotein fraction of zero. Animals afterwards brought out into the light did not develop pentose nucleoprotein as rapidly as did controls. To quote his conclusion, "The cell is dependent on adequate stimulation for the continued development of the nucleoprotein fraction. If it is deprived of this stimulation, the production is reduced or inhibited" (p. 67).

Thus, there seems little doubt that retinal ganglion cells are implicated; but the questions of the time-course and the sequence of events remain to be settled. Chow, Riesen and Newell have considered abnormal only the instance of rather complete disappearance of ganglion cells—a somewhat advanced state. Brattgård found ganglion cells well developed in terms of conventional histological examination, but altered in cell chemistry, in rabbits reared in darkness for 10 weeks. My cats, after 17 weeks of darkness, showed normal ganglion cell bodies, by conventional histological examination, but altered cell processes. That is, the inner plexiform layer, which includes the dendrites of the ganglion cells, was thinner, and the optic tract, which includes the axons of the ganglion cells, was less dense. The significance of the difference in Müller fibre density may be related to Brattgård's results, since one of the functions ascribed to the Müller fibres by some authorities (for example, Polyak[7]) is a metabolic one.

Attempts have been made to avoid the suspected peripheral atrophic reactions by rearing animals in diffuse, non-patterned light. In many such mammalian studies, however, animals were first kept in total darkness for some period prior to such experience, presumably for practical reasons. We have tried to duplicate this period in one such study by Riesen *et al.* Hence, by the time diffuse experience is permitted, the eye may already be retarded in its development, although perhaps not irrevocably if the period was not too long. Even where such a consideration does not apply, it is reasonable to assume that diffuse illumination may involve disuse of peripheral mechanisms, since 'on' and 'off' receptors would operate less frequently. Whether, in fact, rearing from birth under conditions of diffuse stimulation results in peripheral alteration awaits systematic study. In the present experiment, no histological difference could be found between the eye given diffuse stimulation and the eye given normal stimulation; but it should be remembered that this experience was necessarily very limited.

There are a few reports in the literature failing to find neural changes after rearing in darkness. Thus, Goodman[1] kept rabbits in the dark for 6 months, producing a clear behavioural deficit for vision. Unfortunately, data are not presented for the thickness of the inner plexiform layer of the retina, but only for the combined thickness of the optic fibre, ganglion cell, and internal plexiform layers, taken together. Nevertheless, this combined figure is smaller in experimental than control retinas. No counts of the optic tract are reported. But the density of cells in the superior colliculi of experimental brains was slightly greater than in control brains, as was, also, the density of pyramidal cells in the striate cortex. Both findings are consistent with a general notion of reduction of fibre field density. Interestingly enough, the lamina molecularis of the striate cortex, which is almost exclusively a fibre layer, was slightly thicker in controls than in experimental animals. All these differences are admittedly slight; but, since only group averages are reported, it is impossible to apply statistical treatment. The direction of the differences would, in general, support my findings.

Chow[8] kept two monkeys in total darkness for 8 months. The only retinal measure reported, however, was the density of ganglion cells, which did not differ from the control figures. There was no change in cell density in the lateral geniculate. Fibre counts are not reported.

It should be made clear that my findings do not rule out the hypothesis that sensory learning may occur as a necessary part of development. They merely cast doubt on the use of total sensory deprivation as a method of testing the hypothesis. While it might be convenient for psychological theory for sensory deprivation to produce changes limited to central neural structures, it is not convenient, perhaps, for the nervous system itself to make such a distinction.

This work was begun in the University Laboratory of Physiology, Oxford. My thanks are due to Prof. E. G. T. Liddell for the use of facilities and animals, to Messrs. Leach and Chesterman for invaluable advice and help in histological processing of the retinas, and to Mr. R. Hutchison for assistance throughout the entire experiment.

CELL-WALL SYNTHESIS BY *STAPHYLOCOCCUS AUREUS* IN THE PRESENCE OF CHLORAMPHENICOL

By R. HANCOCK and DR. JAMES T. PARK*
Medical Research Council Unit for Chemical Microbiology, Department of Biochemistry, University of Cambridge

During investigations of the effect of chloramphenicol on the level of free amino-acids within growing cells of *Staphylococcus aureus* (strain Duncan)[1] it was necessary to measure the rate at which synthesis of cell material in the presence of the antibiotic was responsible for removal of amino-acids from the internal pool. Since chloramphenicol at the concentration used (50 μgm./ml.) causes complete inhibition of protein synthesis (measured by increase in 5 per cent trichloracetic acid-insoluble L-glutamic acid) in *S. aureus*[2], it was surprising to find that the increase in hot-trichloracetic acid-insoluble nitrogen in the culture was only inhibited to the extent of 70 per cent (measured over a period of 1 hr.). It seemed possible that this increase in the presence of chloramphenicol represented synthesis of the hexosamine-peptide polymer which in many Gram-positive bacteria is the predominant component of the cell wall; in *S. aureus* this polymer contains two hexosamines, glycine, D- and L-alanine, L-lysine and D-glutamic acid[3,4]. Accordingly, in the experiment described in Table 1, cells grown for 60 min. in the presence of chloramphenicol (50 μgm./ml.) were analysed for hot-trichloracetic acid-insoluble nitrogen before and after solubilization of the cell wall by complete digestion with the enzyme lysopeptidase, which specifically degrades the cell wall of *S. aureus* and is without detectable proteolytic activity[5]. It can be seen that all the increase in hot-trichloracetic acid-precipitable nitrogen in the presence of chloramphenicol can be ascribed to an increase in lysopeptidase-sensitive

Table 1

Time (min.)	Optical density of culture at 700 mμ	Hot-trichloracetic acid-insoluble nitrogen (μgm./ml. culture)	
		Control	Treated with lysopeptidase
0	0·35	46	34
60	0·41	63	35
60*	0·69*		

* Culture without chloramphenicol

Chloramphenicol (50 μgm./ml.) was added at time 0 to a culture of *S. aureus* (strain Duncan) growing exponentially in 2 per cent peptone–2 per cent glucose medium. Cells were harvested at time 0, and after 60 min., washed and an aliquot treated with lysopeptidase (50 μgm./ml.) for 15 hr. Hot-trichloracetic acid–insoluble nitrogen was determined on treated and control samples.

Increase in hexosamine (µmoles)	1·3	0	0	0	1·3	0

* Final specific activity, counts/min./µmole.

An equal quantity of an amino-acid uniformly labelled with carbon-14 was added to each of a pair of cultures of *S. aureus* (strain Duncan) growing exponentially in synthetic medium (ref. 1); chloramphenicol (50 µgm./ml.) was added to one flask. After 45 min. at 37° C., cells were harvested and fractionated as described. Samples were taken for radioactivity determinations using 'infinitely thin' samples, and hexosamine was determined by the procedure of Boas (ref. 6).

material, suggesting that under these conditions synthesis of cell-wall material continues although protein synthesis is completely inhibited.

Confirmation of this finding was sought using amino-acids labelled with carbon-14. A method developed in this laboratory was used for preparation of cell-wall fractions which allows rapid sampling, quantitative recovery and avoids the possibility of autolytic degradation during preparation. This procedure will be described in detail elsewhere; it entails extraction of cells with 5 per cent trichloracetic acid at 100° C. for 15 min. and digestion of the residue at 37° with trypsin (500 µgm./ml.) in 0·01 *M* ammonium bicarbonate (*p*H 8·0) until the optical density at 700 mµ ceases to drop; the residue is washed in ammonium bicarbonate and in 1 *N* ammonia. From the following evidence it appears that this fraction consists of all the cell-wall material contaminated with not more than about 5 per cent of cytoplasmic protein:

(*a*) After hydrolysis and separation of the amino-acids by paper chromatography, more than 90 per cent of the ninhydrin-reacting material is accounted for by alanine, glycine, lysine and glutamic acid, the characteristic amino-acids of *S. aureus* cell walls[3]. All the hexosamine of the cell, estimated by the procedure of Boas[6] after hydrolysis in 6 *N* hydrochloric acid for 5 hr. at 105°, is present in this fraction (Table 2).

(*b*) Less than 5 per cent of the radioactivity incorporated into growing cells from labelled non-wall amino-acids appears in this fraction, but between 22 per cent (glutamic acid) and 65 per cent (glycine) from wall amino-acids (Table 2).

(*c*) On treatment with lysopeptidase the turbidity of such preparations falls by 90 per cent, and from preparations containing carbon-14 in all the wall amino-acids 96 per cent of the radioactivity becomes non-sedimentable (3,000*g* for 30 min.) and 31 per cent becomes dialysable. It was considered that the ease of quantitative recovery and the small amount of contamination with cytoplasmic protein made such preparations suitable for studies of cell-wall synthesis.

The incorporation of amino-acids labelled with carbon-14 into the cell wall and protein of *S. aureus* (strain Duncan) during 45 min. growth in synthetic medium[1], together with the effect of 50 µgm./ml. chloramphenicol, is presented in Table 2. Considering the fraction insoluble in hot trichloracetic acid as a whole, the chloramphenicol-sensitive incorporation appears to be exclusively into the protein; incorporation into the cell wall is insensitive to chloramphenicol at this concentration (incorporation of alanine into the cell wall is unaffected by chloramphenicol at concentrations up to 500 µgm./ml.). Over longer periods some inhibition of wall synthesis is observed; this is probably because chloramphenicol prevents the

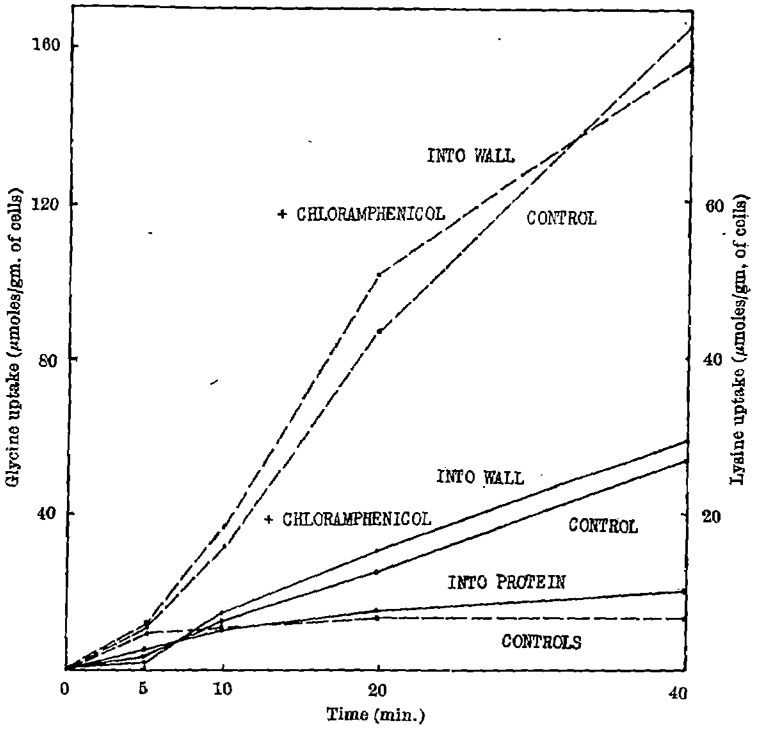

Fig. 1. Rate of incorporation of lysine (——) and glycine (– – –) into *S. aureus H.* Cells were harvested from nutrient broth when the cell population reached 0·5 mgm. dry weight/ml., washed, resuspended at a concentration of 1 mgm./ml., and shaken at 37° C. in the following medium which contained, per ml.: L-lysine, 0·5 µmole; glycine, 0·5 µmole; L-glutamic acid, 2 µmoles; DL-alanine, 2 µmoles; uracil, 20 µgm.; glucose, 4 mgm.; phosphate buffer, *p*H 7·0, 80 µmoles; magnesium sulphate, 1 µmole; manganese chloride, 0·1 µmole; thiamin, 2 µgm.; nicotinic acid, 1 µgm. Uniformly-labelled amino-acid (0·1 µc./ml.) was used and the cells were fractionated as described in the text

formation of the wall-synthesizing system so that wall synthesis is linear, compared with an exponential control. Moreover, the wall synthesized in the presence of chloramphenicol appears to be normal in at least two respects: the ratios of increases in glutamic acid : glycine : alanine : lysine : hexosamine were 1 : 5·8 : 4·2 : 2·0 : 1·8, compared with ratios of 1 : 6·3 : 2·8 : 1·9 : 1·8 in the wall present initially, and the extent of digestion by lysopeptidase (which is probably the result of a highly specific structure in view of the limited specificity of the enzyme[5]) was the same in wall synthesized in the presence and in the absence of chloramphenicol.

It has been found that *S. aureus* (strain *H*) will synthesize cell-wall material under conditions in which amino-acid incorporation into the protein fraction is severely reduced by the absence of essential amino-acids. As shown in Fig. 1, in the presence of L-lysine, alanine, glutamic acid, glycine, uracil and glucose, *S. aureus* (strain *H*) will almost double its wall in 40 min. as measured by the incorporation of lysine or glycine. The rate of synthesis of new wall material is linear, and chloramphenicol (20 μgm./ml.) has no significant effect on this synthesis.

Hence, in both growing cells and cells in which the synthetic activity is directed predominantly towards wall synthesis, chloramphenicol has no inhibitory effect on this synthesis. It is clear from these results that the fraction of bacterial cells insoluble in hot trichloracetic acid cannot be regarded as homogeneous with respect to the incorporation of labelled amino-acids, particularly in the case of the Gram-positive bacteria, where the hexosamine-peptide polymer may account for 30 per cent or more of the material insoluble in hot trichloracetic acid (Park, J. T., unpublished work). It is probable that hexosamine-peptide structural elements similar to those occurring in the Gram-positive cell wall are present also in the wall of Gram-negative bacteria, for example, *Escherichia coli*[7], but in smaller quantity; hence in all bacteria it is advisable to distinguish between amino-acid incorporation into the protein and that into cell-wall structures other than protein.

We are indebted to Dr. M. R. J. Salton for a preparation of lysopeptidase; this work was carried out during the tenure by one of us (R. H.) of a Medical Research Council Scholarship.

A NOVEL TYPE OF AROMATICITY

By PROF. D. P. CRAIG
William Ramsay and Ralph Forster Laboratories, University College, London
AND
N. L. PADDOCK
Research Department, Albright and Wilson, Ltd., Oldbury, Birmingham

THE two ideas of aromatic character and the aromatic sextet are closely bound up together in aromatic hydrocarbon theory, but their association is not invariable, either in theory or, we believe, in practice. We present an outline of the theory of a second type of aromaticity and illustrate its application by reference to the monocyclic phosphonitrilic chlorides $(NPCl_2)_n$, which, certainly for $n = 3$ and 4 and possibly higher, display aromatic character without special preference for a group of six electrons.

Take a ring of $2n$ atoms, n of one species A and, alternating with them, n of a second species B. Let their Coulomb parameters be α_A and α_B, and their resonance integral be β, with non-neighbour interactions neglected. Each A and B has an orbital of the π-type to use in conjugation. If A and B are both carbon, or are carbon and nitrogen, or boron and nitrogen, both orbitals are $p\pi$. If A is carbon or nitrogen and B is phosphorus it is possible that one is $p\pi$ and the other $d\pi$.

The atoms A being numbered $k = 1, 2 \ldots n$ cyclically, the atoms B can be given the numbers $k + 1/2 = 3/2, \ldots n + 1/2$. Using molecular orbital theory of the simplest type, we begin with combinations of the sets A and B with irreducible symmetry:

$$A_l = n^{-1/2} \sum_{k=1}^{n} \exp(2\pi i l k/n)\, \varphi_k$$

$$B_l = n^{-1/2} \sum_{k=1}^{n} \exp\{2\pi i l\,(k + 1/2)/n\}\, \psi_{k+1/2}$$

φ_k denotes the π orbital at the kth centre, and $\psi_{k+1/2}$ that at the $k + 1/2$. l is the ring quantum number with allowed values $0, \pm 1, \ldots n/2$ or $\pm (n - 1)/2$ for n even or odd. Pairs of the same l have now to be combined to form molecular orbitals for the system. This leads in the usual way to a set of second-degree secular equations, one for each l value, of the form:

$$\begin{vmatrix} \alpha_A - \varepsilon & \chi \\ \chi^* & \alpha_B - \varepsilon \end{vmatrix} = 0$$

where

$$\chi = n^{-1} \sum_k \exp(-2\pi i l/2n) \int \varphi_k \mathbf{H} \psi_{k+1/2}\, d\tau$$

$$+ n^{-1} \sum_k \exp(2\pi i l/2n) \int \varphi_k \mathbf{H} \psi_{k-1/2}\, d\tau$$

H being the hamiltonian. Two cases only can occur: one is that of the aromatic hydrocarbons, and the other is distinct but not, so far as we are aware, hitherto recognized as such. They are illustrated in Fig. 1.

For convenience in fixing signs each member of the A set is generated by successive n-fold rotations from the first, and likewise in the B set. Then in case (1) every atom interacts with both its neighbours in the same way, that is,

$$\int \varphi_k \mathbf{H} \psi_{k+1/2}\, d\tau = \int \varphi_k \mathbf{H} \psi_{k-1/2}\, d\tau$$

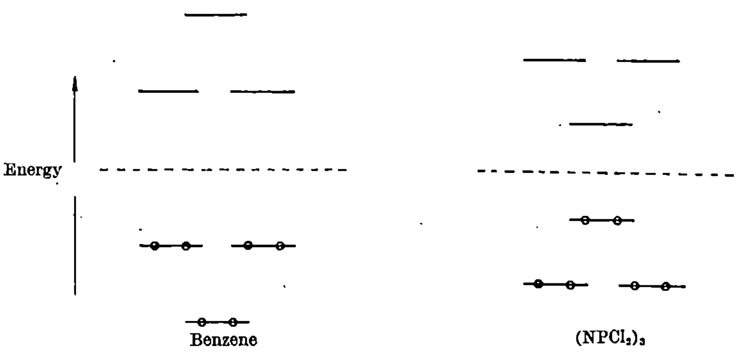

Fig. 2

This holds when A and B use the same species of atomic orbitals, both $p\pi$, or both $d\pi$, and also under somewhat wider conditions, as, for example, when A and B use orbitals which have in common both π-character and character for a reflexion σ_v. In case (2) the interaction of an atom with one neighbour is the negative of that with the other,

$$\int \varphi_k \mathrm{H} \psi_{k+1/2} \mathrm{d}\tau = -\int \varphi_k \mathrm{H} \psi_{k-1/2} \mathrm{d}\tau$$

as illustrated for $p\pi - d\pi$ interactions in the diagram. This case only occurs when A and B use different species of atomic orbitals and not always then. The orbitals must differ in character under σ_v.

Returning to the secular equation, for case (1) we find $\chi = \pm 2\beta \cos(\pi l/n)$, the sign depending on how the set of A orbitals is oriented, by initial choice, relative to the set of B. For benzene ($n = 3$, $\alpha_A = \alpha_B = \alpha$) this leads to the usual results for molecular orbital energies: $\varepsilon_0 = \alpha \pm 2\beta$, $\varepsilon_{\pm 1} = \alpha \pm \beta$ (both twice). In case (2) $\chi = \pm 2i\beta \sin(\pi l/n)$ leading to the energy expression

$$\varepsilon_l = (\alpha_A + \alpha_B)/2 \pm \{(\alpha_A - \alpha_B)^2 + 16\beta^2 \sin^2(l\pi/n)\}^{1/2}/2$$

For $n = 3$, $\alpha_A = \alpha_B = \alpha$, $\varepsilon_0 = \alpha$ (twice) $\varepsilon_{\pm 1} = \alpha \pm \sqrt{3}\beta$ (both twice). This example shows that the lowest energy is associated with ε_0 in case (1), with $\varepsilon_{\pm 1}$ in case (2); to be realistic we should allow α for the $2p\pi$ orbitals (for example, nitrogen) to be more negative than the $3d\pi$ (for example, phosphorus), and putting $\alpha_N = \alpha_P + \beta$ for purposes of illustration leads to the results shown in Fig. 2. The dotted line is placed at α_C for the benzene calculation and at $(\alpha_N + \alpha_P)/2$ for $(NPCl_2)_3$.

The differences between cases (1) and (2) run deep, but we wish now only to emphasize the matter of the aromatic sextet. The states $l = 0$ always lie at the extremes of the energy band in case (1), so that the top occupied orbital is always doubly degenerate in hydrocarbons. Closed shells associated with typically aromatic inertness therefore contain $4n+2$ electrons; $4n$ electron systems leave a half-filled orbital and are not aromatic. This is, of course, Hückel's rule, and the particular example of the stability of six compared with four and eight electrons supports the notion of the sextet. In case (2) the two states $l = 0$ have different symmetries and always (any n) lie adjacent to one another half-way up the energy band. Since except for exact equality in the electronegativity parameters of A and B these states are non-degenerate, a closed shell is obtained for any even number of electrons, both $4n$ and $4n + 2$. In the planar system in case (2) there is no preference for six over four or eight electrons, therefore no special stability is expected for a sextet. On the contrary, the energy per π-electron rises slowly but monotonically with the number of electrons to a limiting value, so that for planar molecules eight electrons are more stable than six. Fully in harmony with this is the fact that both the trimeric and tetrameric ($n = 3$ and 4) phosphonitrilic chlorides show unexpected stability and equal bond-lengths, both roughly speaking displaying equally well-developed aromaticity, in contrast to benzene and *cyclo*-octatetraene.

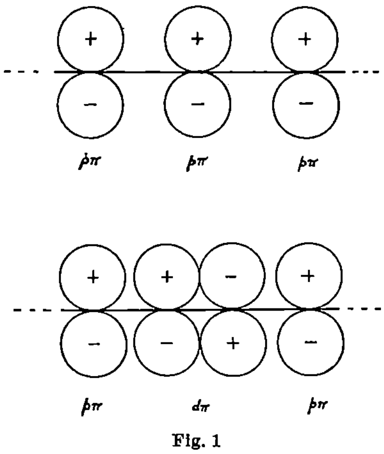

Fig. 1

In the phosphonitrilic halides there is the further consideration that the $p\pi - d\pi$ system is less affected by puckering than is the $p\pi - p\pi$ system, so that the probable non-planarity of the tetramer is not a serious hindrance to maintenance of aromatic interactions and need not affect arguments based on plane structures.

Conventional calculations of π-electron energies made for the case $\alpha_N = \alpha_P + \delta$, where δ is now used for the P–N resonance integral, are compared with the hydrocarbons in Table 1. Values are given per π-electron. We emphasize that the choice of α-values is an arbitrary one, and merely serves to indicate the pattern of the problem.

Table 1. CALCULATED ENERGIES PER ELECTRON

No. of electrons	4	6	8	10	12
Aromatic hydrocarbons $\alpha_C +$	$1{\cdot}0\beta$	$1{\cdot}33\beta$	$2{\cdot}20\beta$	$1{\cdot}30\beta$	$1{\cdot}24\beta$
$(NPCl_2)_n$ $\alpha_P +$	$1{\cdot}78\delta$	$1{\cdot}87\delta$	$1{\cdot}89\delta$	$1{\cdot}90\delta$	$1{\cdot}90\delta$

The alternation of values shown by the hydrocarbons, corresponding to the $4n + 2$ *versus* $4n$ rule, is not shown by the phosphonitrilic halides. Both series approach limiting energies per π-electron with increasing size; but in the hydrocarbons successive members fall above ($4n + 2$ electrons) and below ($4n$), while in the second case the approach to the limit is always from below, showing that if π-electrons were the only consideration, bigger molecules would be favoured over smaller ones. These quantitative results are, however, secondary to the main point, which is the distinction between the two types of aromaticity; this distinction depends on symmetry and is independent of the more disputable quantitative features of π-electron theories.

Variation in the Speed of Rotation of the Earth since June 1955

Time and frequency comparisons have been made since June 1955 between the National Physical Laboratory, Teddington, and the U.S. Naval Observatory, Washington, with the ultimate purpose of establishing the value of the transition frequency of cæsium, (4,0) $\rightleftharpoons$ (3,0), in terms of the second of Ephemeris Time based on the orbital motion of the Moon[1,2]. The second of Ephemeris Time is being determined at the Naval Observatory from photographic observations of the Moon, and will be reported on later.

As an intermediate step, the frequency of cæsium is currently being determined with respect to the second of Universal Time, called UT2, which is based on the rotation of the Earth. This frequency is denoted ν_U. The intervals between time signals from *WWV* (Washington, D.C., U.S.A.) and *GBR* (Rugby, U.K.) are measured at the National Physical Laboratory in terms of the cæsium standard, and at the Naval Observatory in terms of UT2. By using signals near the first of each month, the average frequency for the intervening month is intercompared with a probable error of 3 parts in 10^{10}.

If it is assumed that the time occupied by a specified number of vibrations of the National Physical Laboratory standard is constant, we may use it to determine changes in the speed of rotation of the Earth. Such changes would be indicated by changes in ν_U. The precision of the cæsium standard is so high that the accuracy with which the changes in speed of rotation can be determined depends almost entirely on the accuracy with which Universal Time can be determined. The results given here are based on observations made with the photographic zenith tubes at Washington, D.C., and Richmond, Florida, which are known to be instruments of high accuracy.

In order to interpret changes in ν_U, it is necessary to describe the types of variation in speed of rotation and how UT2 is computed.

There are three types of variation in speed: secular, irregular and periodic. The first, due to tidal friction, is too small to be significant here. Irregular variation refers to departures from the average speed of rotation which continue for the order of 5 or 10 years. This effect has been surmised but not previously exhibited. Periodic terms have been found with periods of 1 year, 0·5 year, 27·6 days and 13·6 days[3]. The first two of these terms comprise what is known as the seasonal variation.

By international agreement, an empirical correction for seasonal variation has been applied since January 1, 1956, in obtaining the time called UT2. The formula adopted by the Bureau International de l'Heure is:

$$\Delta SV = 0{\cdot}022^s \sin 2\pi t - 0{\cdot}017^s \cos 2\pi t - 0{\cdot}007^s \sin 4\pi t + 0{\cdot}006^s \cos 4\pi t$$

where t is the fraction of a year.

The terms of period 27·6 days and 13·6 days are eliminated by the smoothing process used in obtaining the adopted UT2 published in the *Time Service Bulletins* of the U.S. Naval Observatory. Hence, UT2 represents, in effect, the speed of rotation of the Earth when freed of periodic terms.

The values of ν_U since June 1955 are shown in Fig. 1. In addition to month-to-month variations which are of an accidental nature, there is seen to be a systematic trend. The length of the day was a minimum about September 1955 (speed of rotation at maximum) and has been increasing at a practically constant rate since then (speed of rotation decreasing).

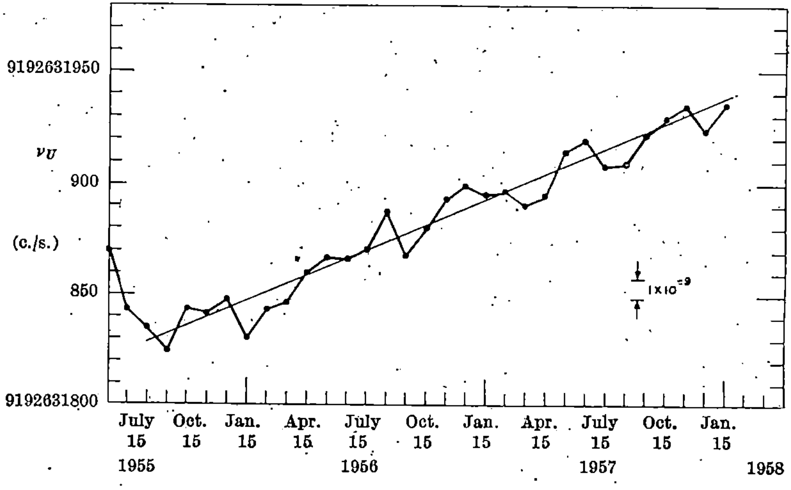

Fig. 1. Frequency of the cæsium resonance in terms of UT2

ν_U can be well represented since September 1955 by a straight line. This means that the seasonal variation for the past two years as determined with the aid of the cæsium standard is practically the same as determined with the aid of quartz-crystal clocks for several years previous to 1955.

Fig. 1 represents the non-periodic portion of the variation in the speed of rotation of the Earth. Since September 1955, this has been a constant deceleration of 5 parts in 10^9 per year, equivalent to an increase in the period of rotation of 0·43 msec. a year. This deceleration is about fifty times as large as that attributed to tidal friction. It is probable that it represents the irregular variation, but further observations are needed to confirm this.

Effect of the Earth's Equatorial Bulge on the Life-time of Artificial Satellites and its use in determining Atmospheric Scale-Heights

PREVIOUS correspondents[1-3] have discussed the derivation of a simple formula for the life-time T of an Earth satellite. The formula concerned is:

$$T = \frac{3}{4}Pe\left(1 + \frac{7}{6}e + \frac{1}{2}kae\right)\Big/\left(-\frac{dP}{dt}\right) \qquad (1)$$

where P is the period, dP/dt the rate of change of period with time, e the eccentricity, a the semi-major axis and $1/k$ the atmospheric scale-height. This formula is valid provided e is both sufficiently small and sufficiently large, and the last two terms on the right-hand side (given here for the first time) indicate the limitations on e.

From various sets of available orbit data, I find that the descent dates predicted by (1) vary with the epoch of the data, more recent data leading to earlier descent dates. For the Sputnik 1 sphere ($1957\alpha_2$), data of October 15 give January 30 (± 4), whereas data of November 9 give January 18 (± 2). The actual descent date was about January 2. For Sputnik 2 (1957β), data of November 9 give June 24 (± 10), whereas data of February 4 give April 30 (± 1). Although these dates refer strictly to the time when the orbit becomes nearly circular, they should be only a few days short of the descent dates.

This shortening of the life-time is attributed to the fact that the perigee points of both satellites have been rotating slowly towards the equator and hence, on account of the equatorial bulge, into denser air. The perigee of sphere $1957\alpha_2$ moved from 42° N. to 5° N. during its life-time; whereas for 1957β, the perigee was initially at about 53° N., and will reach the equator by March 19. An equatorial radius is in excess of a radius at latitude 45° by 11 km., and so the bulge is equivalent to an air-density change of about 60 per cent in the 200-km. altitude region. Formula 1 should therefore not be applied without considering the latitude variation of perigee. The neglect of this effect in Scott's[2] estimates happened to compensate for the omission of the last two terms in (1), so leading to surprisingly good predictions.

My attention was first directed to the effect of the equatorial bulge on perigee air-density ρ by the values in Table 1, which were derived from the formula:

$$\rho = \frac{1}{3\varkappa}\frac{(1-e^2)^{1/2}}{(1+e)^2}\left(\frac{2ke}{\pi a}\right)^{1/2}\left(-\frac{dP}{dt}\right) \qquad (2)$$

where $\varkappa = SC_D/m$, S being the effective cross-sectional area and m the mass of the satellite, and C_D the drag coefficient. (This formula is valid so long at e is not too small; and, in all cases considered, the contributions from higher-order forms and the effect of the Earth's oblateness amount to only of the order of a per cent.)

Perigee air-density values cannot be guaranteed to better than about 30 per cent on account of uncertainties in k and $\varkappa$. Density ratios relating to the same satellite object are, however, independent of k and $\varkappa$ and should be accurate to a few per cent. Thus the perigee air-density for 1957β increased between November 9 and February 3 by a factor of 1·51(±0·06). The change in perigee distance between two epochs can be shown to correspond to a change of density of approximately

Table 1. VALUES OF AIR DENSITY IN THE REGION OF 200-KM. ALTITUDE

Object	Sphere, $1957\alpha_2$*	Sphere, $1957\alpha_2$*	$1957\alpha_1$†	Rocket, 1957β‡	1957β‡
Epoch of data	October 15	November 9 (approx.)		February 3	
Perigree latitude	37° N.	26° N.	26° N.	49° N.	19° N
Perigree height (km.)	206 (±7)	201 (±4)	202 (±4)	211 (±4)	197 (±1)
Perigree air density (gm./c.c.)§	$5·4\times10^{-13}$	$6·7\times10^{-13}$	$7·3\times10^{-13}$	$4·6\times10^{-13}$	$7·0\times10^{-13}$

* C_D taken equal to 2.

† $\varkappa$ taken equal to 1·8 times that of sphere $1957\alpha_2$ (as derived from the ratio of their initial rates of change of period with time).

‡ $\varkappa$ taken equal to 5–6 times that of rocket $1957\alpha_1$ on account of its greater mass.

§ Scale-height $1/k$ taken to be 25 km. Equation 2 shows that ρ varies inversely as the square root of the scale-height.

$$\rho/\rho_0 = (ae_0/a_0e)^{1/2} \qquad (3)$$

and this amounts to only 1·17 (± 0·01) for 1957β between November 9 and February 3. The discrepancy between these two factors, amounting to 1·29 (± 0·05), can be satisfactorily accounted for by the increase of 9·8 km. in the Earth's radius between 49° N. and 19° N. The value obtained for the atmospheric scale-height is then 39 (± 6) km. The data for perigee-height for 1957β in Table 1 enables the scale-height to be determined as 34 (± 11) km.

For sphere $1957\alpha_2$ the height data above are not sufficiently accurate for the scale-height to be found; but use can be made of the fact that 3·7 km. of the change arises from the equatorial bulge. Of the observed increase in air density by a factor 1·24 (± 0·05), a factor 1·08 (± 0·02) of this arises from the decrease in perigee distance as calculated from equation 3, so leaving a factor of 1·15 (± 0·06) attributable to the 3·7-km. change in height. This leads to a value of 26 (± 9) km. for the scale-height.

More accurate orbital data, particularly on the rate of change of period, are needed to take full advantage of the above method. It may then be possible to study the variations of scale-height with latitude.

Application of the Kurie Plot to the Standardization of Pure Beta-Emitters

THE standardization of pure β-emitting nuclides becomes increasingly difficult as the energy of the radiation decreases, because of absorption and scattering effects which occur at the low-energy end of the β-spectrum. It may be possible to circumvent these effects by a technique employed by Waggoner, Moon and Roberts in connexion with a magnetic β-ray spectrometer[1]. This method consists of extrapolating to zero the straight Kurie plot which should be obtained for a single allowed β-ray transition. It is the purpose of this communication to show the relation between the slope of the Kurie plot and the absolute disintegration-rate of a radioactive source, and to describe the proposed method of application to 4π-counting.

The notation adopted is that used by M. E. Rose[2]. For the sake of clarity, simplified equations are used which refer to allowed β-spectra only. The β-spectrum can be represented by a simplified form of the well-known Fermi equation:

$$N(W)\mathrm{d}W = K^2(W_0 - W)^2 pWF(Z,W)\mathrm{d}W \qquad (1)$$

where $N(W)\mathrm{d}W$ is the probability per unit time that an atom will emit a β-particle in the energy range W to $W + \mathrm{d}W$; p is the momentum of the β-particle and W is its total energy; W_0 is the energy released in the nuclear transition; $F(Z, W)$ is the Coulomb field factor (Z referring to the daughter nucleus) and K^2 is a constant independent of W. The Coulomb field factor is also known as the Fermi function, and has been well tabulated for a range of Z and W values[2,3]. A measurement of the spectrum $N(W)\mathrm{d}W$ is made by means of a β-ray spectrometer the transmission factor of which is T. T is defined as the fraction of the particles emitted in a given energy-range detected by the spectrometer counter. If the number of atoms in the source is n, then the number of particles detected per unit time by the counter in the energy interval W to $W + \mathrm{d}W$ is

$$N_\beta(W)\mathrm{d}W = nTN(W)\mathrm{d}W \qquad (2)$$

where $N_\beta(W)\mathrm{d}W$ has been corrected for background and dead-time.

Equations 1 and 2 can be rearranged to give

$$\left(\frac{N_\beta(W)}{pWF(Z,W)}\right)^{1/2} = (nTK^2)^{1/2}(W_0 - W) \qquad (3)$$

which is the equation used for obtaining the Kurie plot. The left-hand side of (3) is plotted against W, as shown in Fig. 1. The graph is linear until the low-energy region is reached, and then deviates from a straight line because in this region the transmission T varies with the energy W. The variation is caused by the absorption and scattering of the low-energy β-particles. Over that portion of the Kurie plot which is linear, T is constant, and the square of the slope gives nTK^2, that is:

$$\tan^2\theta = nTK^2 \qquad (4)$$

By definition

$$\lambda = \int_1^{W_0} N(W)\mathrm{d}W \qquad (5)$$

where λ, the decay constant, is the probability of decay per unit time, and from (1):

$$\int_1^{W_0} N(W)\mathrm{d}W = K^2 \mathrm{f}(Z,W_0) \qquad (6)$$

where

$$\mathrm{f}(Z,W_0) = \int_1^{W_0} (W_0 - W)^2 pWF(Z,W)\mathrm{d}W \qquad (7)$$

Also, the law of radioactive decay can be expressed in magnitude as:

$$N_0 = \lambda n \qquad (8)$$

where N_0 is the number of atoms disintegrating in unit time.

Therefore, by rearranging (5), (6) and (8):

$$N_0 = nK^2\mathrm{f}(Z,W_0) \qquad (9)$$

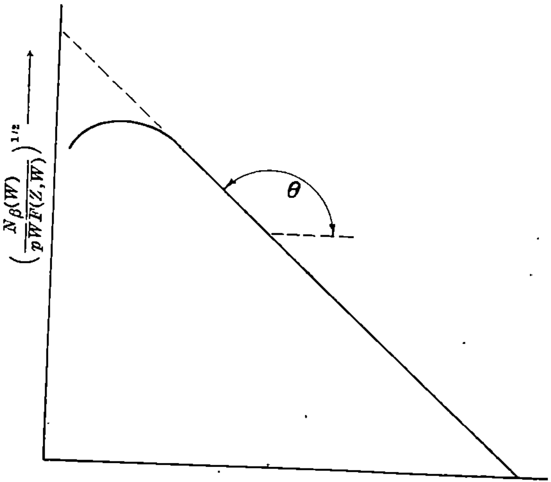

Fig. 1. Kurie plot of a pure β-emitter, according to equation (3); $\tan^2\theta = nTK^2$

and combining (4) and (9)

$$N_0 = \frac{\mathrm{f}(Z,W_0)}{T} \cdot \tan^2\theta \qquad (10)$$

Numerical values of $\mathrm{f}(Z,W_0)$ have been extensively tabulated[4]. If T is also known, then the absolute disintegration-rate of a radioactive source can be derived directly from the slope of the Kurie plot by using (10).

A β-spectrometer for this work need not possess high resolution, but it is necessary that its transmission be accurately known, and that its response either be linear or also accurately known. It would seem that 4π-counters are ideally suited in this first respect, because their transmission factor over the linear portion of the Kurie plot is unity. It is also possible to construct gas proportional counters the response of which is linear, by taking care to keep the gas gain constant[5]. Thirdly, it is necessary, over the energy-range which is of interest, that the β-particle shall expend its entire energy in the sensitive volume of the counter. This can be arranged by operating the counter at a suitable high pressure[6]. The design of a suitable high-pressure proportional counter is therefore being investigated and the accuracy of this method, compared with integral $4\pi\beta$ counting, is being assessed.

This work forms part of the research programme of the National Physical Laboratory, and is published by permission of the Director.

Photoelectric Response of Selenium-type Photovoltaic Cells to X-Rays

A COMMERCIALLY available selenium-type photovoltaic cell was irradiated with X-rays produced with a commercial type of low-voltage X-ray tube with a thermionic cathode and an inclined copper target. Lead covers with circular apertures of different diameters were placed over the photocell to alter the flux of X-rays on the surface of the cell at a constant X-radiation intensity, and the X-radiation intensity was varied by changing the anode current of the X-ray tube. Fig. 1 shows a family of curves representing the photocell current, I_p, as a function of the X-ray tube anode current, I_a, with the anode voltage, V_a, as parameter, the curves having been obtained with a distance of 25 mm. between the photosensitive surface of the cell and the centre of the target of the X-ray tube, 17·5 mm. of the distance being in the vacuum space of the tube, 1·5 mm. the thickness of its cylindrical envelope of soda-lime glass, and the remainder of the air space between the tube and the photocell surface. The curves marked *A* refer to an aperture of 240 mm.^{2} in the lead cover, and those marked *B* refer to a 60-mm.^{2} aperture.

The characteristics of Fig. 1 indicate a linear relation between photoelectric response and X-radiation flux irrespective of whether the flux is changed by altering the X-radiation intensity or by varying the size of the area of irradiation.

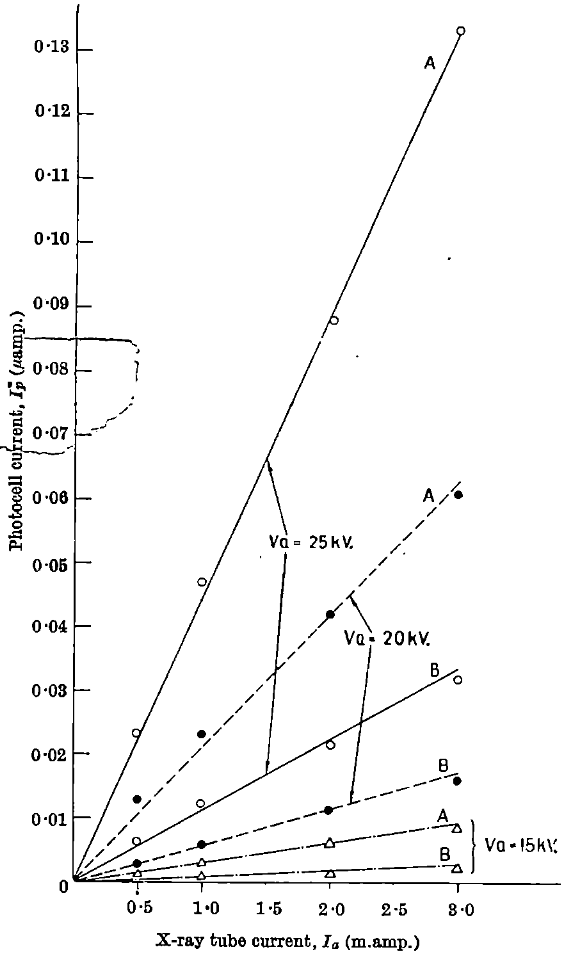

Fig. 1. Curves *A*, irradiation area, 240 mm.^{2}; curves *B*, irradiation area, 60 mm.^{2}

Increasing the aperture of the lead cover over the photocell to a diameter of 25 mm., compared with 17·5 mm. for obtaining the curves *A* in Fig. 1, demonstrated the reduction of radiation intensity towards the boundary of the X-ray beam. The photocurrent response indicated that the X-radiation flux increased only by 50 per cent, whereas it would have doubled if the X-radiation intensity had been uniform over the whole area of the aperture.

A second photocell of the same type gave a similar photoelectric response characteristic, but all photocurrent values were reduced to one-third of those of Fig. 1, although the two cells had the same photoelectric sensitivity to light. The fact that both cells were equally sensitive to light but differently sensitive to X-rays may probably be interpreted in terms of light being effective only at the surface of the photosensitive layer and X-rays being effective in its depth, and that there was a difference in the thickness and/or the structure of the photosensitive layers of the two cells. The depth effect of X-rays may possibly in part also account for the dependence of the photoelectric response on the anode voltage of the X-ray tube.

Plasticity of Graphite

THE creep behaviour of graphite in the temperature range 1,300–2,000° C. has been examined for the first time. The experiments were carried out by applying loads to cantilevers heated *in vacuo* by the passage of an electric current and to spring specimens heated in a high-temperature high-vacuum furnace. The specimens were made in the laboratory by extruding a wide range of raw materials (pitch coke, petroleum coke, lamp black, cellulose and natural graphite). Springs of rectangular section were also machined from commercially manufactured materials (reactor graphite and commercial electrode graphite). The apparatus and techniques used in these experiments were similar to those used in dynamic experiments previously described[1].

It was found that, for a wide range of temperatures, raw materials, specimen geometries, flexural and torsional stresses, the creep deformation could be statistically fitted within the limits of experimental error to the function:

$$D_t = A + k \log_{10} t + Bt \qquad (1)$$

where D_t is strain at time t and t is time (min.).

A, *k* and *B* are constants for each experiment. Similarly, the creep recovery on removing the load conformed to the function:

$$D_t^1 = A^1 + k^1 \log t \qquad (2)$$

A typical creep curve is shown as a linearized plot in Fig. 1*a*. Fig. 1*b* is a plot of the deviations of the experimental points from the function determined by the method of least squares.

The coefficients *k* and *B* were linearly dependent on the applied stress at constant temperature and were related to the absolute temperature as follows:

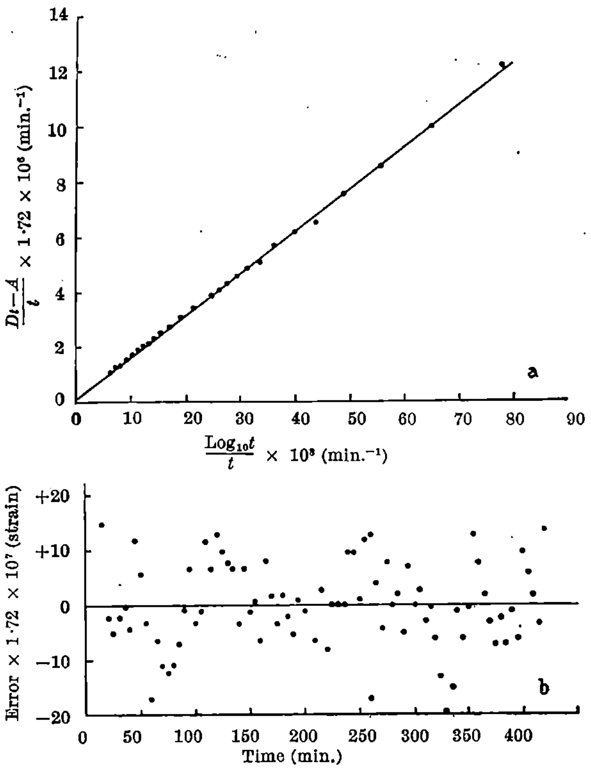

Fig. 1. (*a*) Linearized plot of typical creep curve; equation, derived by method of least squares: $D_t = 0{\cdot}87 \times 10^{-3} + 7{\cdot}0 \times 10^{-8}\, t + 8{\cdot}9 \times 10^{-5} \log_{10} t$. Graphitized cellulose carbon spring No. *C*12, temperature 1,560° C., maximum stress $8{\cdot}9 \times 10^7$ dynes/cm.^{2}. (*b*) Deviation of experimental points from the function derived by the method of least squares

$$k = K(\text{stress}) \exp\left(-\frac{\Delta E}{RT}\right) \qquad (3)$$

and

$$B = K^1(\text{stress}) \exp\left(-\frac{\Delta E^1}{RT}\right) \qquad (4)$$

where K and K^1, and ΔE and ΔE^1 are constants, R the gas constant and T the absolute temperature. The stress relationship is demonstrated in Fig. 2.

The linearity of the stress–strain relationship made possible the use of specimens in which the applied stress was not uniform throughout, and strengthens the belief that equation 1 relates to the structure of the graphites examined and not to the particular stress systems applied to the specimens.

The available evidence shows that $K = C/M$ in equation 3, where M is the elastic modulus at room temperature appropriate to the stress system applied and C a constant for all the materials studied. This is illustrated in Table 1. The product $\frac{k}{\text{stress}} \times M$ is a constant at each temperature.

It is therefore reasonable to rewrite equation 3 as follows:

$$k = \frac{C}{M}(\text{stress}) \exp\left(-\frac{\Delta E}{RT}\right) \; (C \simeq 13) \qquad (5)$$

Since modulus and stress should depend on the same function of the density, this treatment eliminates the effect of density from equation 5. The constant ΔE in equation 5 was found to have a value of 21 kcal./mole for petroleum coke and cellulose carbon springs, which were studied over a range of temperatures. Since the correlation between $\frac{k}{\text{stress}}$ and $\frac{1}{M}$ was found to be true at two temperatures, and if C is assumed to be a universal constant in equation 5, this leads to one value of 20 kcal./mole for all the materials, in reasonable agreement with the value quoted above. No such relationships were found for the coefficient B.

By examining repeated identical cycles of creep and recovery, it was shown that the Bt term in

equation 1 contributed to a permanent set which could be removed only at graphitizing temperatures.

The effect of the gross grain structure on the plastic behaviour of graphite is not noticeable, since it appears possible to relate the transient term to the elastic modulus which, it has already been demonstrated[1], depends on the crystallite parameters of the 'grist' material. The steady-state term has not yet been found to be correlated with any of the known parameters of the materials.

This work forms part of a study of the plastic behaviour of graphite carried out under contract to the Atomic Energy Research Establishment, Harwell.

Ease of Reduction of a Series of Coals and its Relation to their Structure

WE wish to report an interesting variation in the ease of reduction of coals and solvent extracts of coals with change in ash-free carbon content (change in rank).

Two methods of reduction, each initially involving electron transfer, have been used. They are the reduction of coal with lithium in ethylamine[1] and the controlled potential electrolysis of dimethylformamide extracts of coal in dimethylformamide. The latter was carried out in a cell similar to that used by Bergman and James[2] at $-2{\cdot}2$ V. (*versus* mercury pool) with $0{\cdot}1\,N$ tetraethylammonium iodide as supporting electrolyte: the electrolysis was followed by acetylation of the products *in situ* with acetic anhydride to prevent oxidation of hydroquinones produced from quinones present in the coal. Proton addition from the solvent normally follows electron addition from the lithium or from the mercury cathode[3]. In known aromatics a greater degree of reduction is effected by lithium in ethylamine than by electrolysis (for example, naphthalene is reduced to octalin[1] and to dihydronaphthalene[4] respectively).

The elementary analyses and infra-red spectra of the products showed that reduction had taken place; the electricity consumed in the electrolyses and the polarographic behaviour, in the case of solvent extracts, also supported this conclusion. Various measures of the degree of reduction are presented graphically in Fig. 1 as a function of the carbon content of the coal. The proportion of the reduced coals soluble in cold pyridine varied widely with the carbon content of the coal, and was very high for the coking coals (86–90 per cent carbon); it appears to be a valid and convenient index of the degree of reduction, and is also shown in Fig. 1. The results show that the extent of reduction of the coals increases markedly with increase in rank up to about 89 per cent carbon content and falls rapidly thereafter; that is, both low-rank coals and the anthracite show a marked reluctance, compared with the intermediate coking coals, to suffer addition of hydrogen. The solvent extracts show changes in the same sense, but less marked.

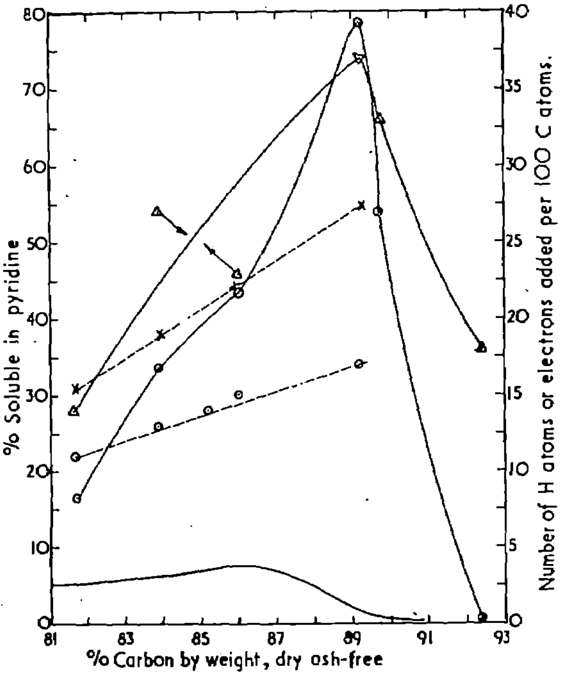

Fig. 1. Reduction of coals and coal extracts. ——, Coals: △, number of hydrogen atoms added per 100 carbon atoms (from elementary analysis); ⊙, per cent reduced coal soluble in pyridine (cold); —, per cent original coal soluble in pyridine (cold). – – – –, Coal extracts: ×, number of electrons added per 100 carbon atoms (from current consumption); ⊙, number of hydrogen atoms added per 100 carbon atoms (from elementary analysis). In calculating these figures the product reduced and acetylated at $-2{\cdot}2$ V. has been compared with that reduced and acetylated at $-1{\cdot}0$ V. where only quinone groups are reduced (ref. 12)

A further point arises from polarography of the products of electrolysis: although polarograms of the electrolysed solutions showed complete absence of waves, those of the products isolated from these solutions showed partial reappearance of the waves associated, in previous work[5], with aromatic reduction. This effect was most noticeable with the products from the low-rank coal extracts. The re-emergence of waves in the polarograms of the isolated products indicates a failure of the ions to complete the reduction by adding protons. This reluctance of the hydrocarbon ions to add protons evidently decreases with increase in rank of the coal.

The only explanation we are able to suggest at present for these changes in behaviour with rank concerns the deformation from planarity which in general occurs when hydrogen is added to aromatic systems, or more specifically, on proton addition to a hydrocarbon ion. Presumably this deformation of structure can only occur to a limited extent with low-rank coals, which indicates that the aromatic systems are held in a rigid cross-linked structure. The greater ease of deformation in the coals of higher rank would therefore indicate less rigidity and consequently less cross-linking of the aromatic systems. This idea has already been suggested by Given[6] in connexion with the poor reduction of a low-rank coal with lithium in ethylamine. Some confirmation for the idea can be deduced from the work of J. K. Brown[7], who, from an estimate of the aliphatic/aromatic hydrogen ratio determined spectroscopically in a series of coals, concluded that in low-rank coals the greater part of the hydrogen is present in methylene groups with little appearing on aromatic rings and still less as —CH_3 (Brown, J. K., private communication, and ref. 8). This, together with Hirsch's[8] estimation of aromatic cluster size, suggests that the aromatic clusters in low-rank coals have little replaceable hydrogen; if therefore the clusters are highly substituted by alkyl side-chains the function of which is, in the main, to join one cluster to another, then the whole molecule, consisting of a number of clusters each tied to others by numerous linkages, would probably be particularly resistant to deformation. This resistance could slow down materially the rate of addition of hydrogen, and might even render the addition thermodynamically impossible. I. Wender (private communication, and ref. 10) has recently achieved a considerable degree of reduction of a low-rank coal with lithium in ethylene diamine at 100–117°. This suggests that the resistance to deformation slows down, but does not entirely prevent, addition of hydrogen.

The work of Brown and Hirsch also shows that there must be less aliphatic material and more aromatic hydrogen as rank is increased, in accordance with a more readily deformed structure. The argument applies to the coals studied up to about 89 per cent carbon content; the decreased ease of reduction beyond this point is probably due to the rapid increase in aromatic cluster size which is generally believed[7,9,11] to occur at this point.

Electrocapillary Action of Corrosion Inhibitors

Indelli and Pancaldi[1] and I[2] have compared some characteristic phenomena occurring at the interface of a dropping mercury microelectrode and electrolyte solutions with phenomena encountered in corrosion inhibition[2]. It was found[2] that the effectiveness of numerous corrosion inhibitors is reflected in their ability to suppress various polarographic maxima (abnormal current peaks in the current-voltage curves of the mercury microelectrode). In particular, it was shown that the order of relative inhibiting effectiveness of a number of amine inhibitors (for the iron – sulphuric acid system) is the same as that of their effectiveness in suppressing certain polarographic maxima. These amines (both aliphatic and aromatic) were most effective in suppressing maxima corresponding to the negative branch of the electrocapillary curve at which mercury is negatively charged with respect to the solution. This is consistent with Mann's[3] conclusion that amines inhibit the corrosion of iron in sulphuric acid by becoming adsorbed on the cathodic areas of this metal. It was thus demonstrated that significant similarities exist between the processes involved in polarographic maxima and their suppression, on one hand, and in metallic corrosion and its inhibition, on the other[4]. Campbell[5] has also employed polarographic techniques in detecting corrosion inhibitors.

Based on similar reasoning, De[6] has recently proposed "A Unified Theory of the Mechanism of Inhibition of Corrosion of Iron in Acid and Neutral Media based on the Electrocapillary Behavior of Ions". This theory provides a basic approach to many aspects of corrosion inhibition processes. A few years ago, I obtained some experimental results on the electrocapillary properties of representative corrosion inhibitors; these results are quite pertinent to the above theory. Mercury was employed, since electrocapillary studies with solid metals present serious experimental difficulties.

The electrocapillary curves of mercury were obtained in 1 *N* sulphuric acid, 1 *N* hydrochloric acid and 0·1 potassium chloride by applying a potential across a dropping mercury electrode and a mercury pool. The dropping time, which is proportional to the surface tension of mercury, was employed in plotting the electrocapillary curves. The results obtained with aliphatic amines are shown in Fig. 1. It is seen that the inhibiting behaviour of these amines as discussed by Mann[3] is reflected in their electrocapillary properties; that is, their overall effect on the electrocapillary curve of mercury, their specific effect on the negative branch of the curve, and the shift of the electrocapillary maximum towards less negative values, increase with increasing molecular weight of the amines. This behaviour, of course, indicates that in acid solutions amines are adsorbed in the form of ammonium ions, $RNH_3{}^+$. The lower members of the aliphatic amines, namely, methyl- and ethyl-amine, in the concentration range considered, affected the electrocapillary curve only to a small extent.

Representative inorganic inhibitors were also tested for their effect on the electrocapillary curve of

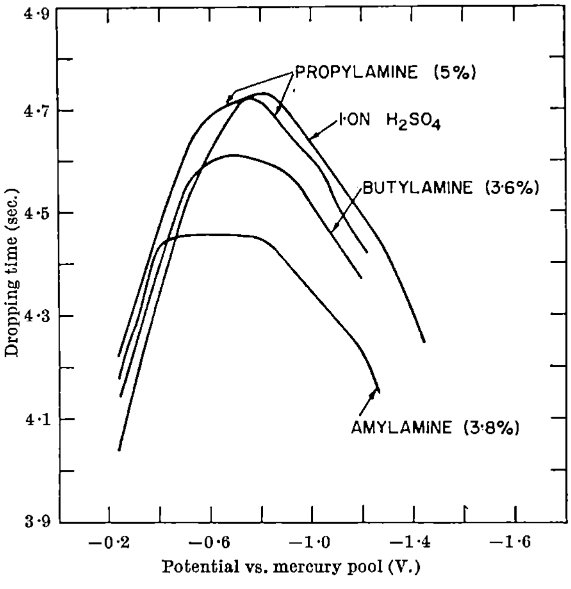

Fig. 1. Effect of aliphatic amines on the electrocapillary curve of mercury in sulphuric acid

mercury in 0·1 *N* sodium chloride and 0·1 *N* potassium chloride solutions. The following inhibitors were included at a concentration of 0·03 per cent: sodium tetraborate, sodium benzoate, trisodium orthophosphate, potassium dichromate, sodium nitrite and sodium silicate. All these inhibitors affected the positive (less negative) branch of the electrocapillary curve, indicating the adsorption of the anions of these inhibitors on the positively charged mercury surface. Such behaviour in this type of inhibitors is among the requirements of De's theory regarding solid metals.

In electrocapillary phenomena, particularly from the point of view of corrosion inhibition, competitive adsorption must be of importance. In aqueous solutions a number of ions are usually present which can compete for sites on a metal surface. Phenomena associated with such competitive processes should, therefore, be taken into consideration in an electrocapillary approach to corrosion inhibition. With this in mind, an attempt was made to determine the action of a given inhibitor on the electrocapillary curve which was obtained in the presence of another inhibitor. Among the above inorganic inhibitors studied, it was found that the effect of potassium dichromate on the electrocapillary curve was independent of any other inhibitor present. Alternatively, in a solution containing potassium dichromate, addition of one or more of the rest of the inhibitors had no further effect on the electrocapillary curve. This result can be considered as representing a case of competitive adsorption where dichromate ions are the most strongly adsorbing among the ions considered. They can thus displace the other ions from the mercury surface; the reverse process does not take place at the concentrations employed. Competitive adsorption in corrosion inhibition could probably be studied indirectly—by dissolution rates and/or electrode potential measurements—much more conveniently than by the electrocapillary action of inhibitors on solid metals.

These results on mercury cannot, of course, serve as a direct verification of the electrocapillary action of corrosion inhibitors; but they will encourage electrocapillary studies on solid metals.

Influence of Metallic Ions on the Reaction of Ethylene Diamine with Epinephrine and Norepinephrine

THE reaction of ethylene diamine with epinephrine (and norepinephrine) leads to the formation of a highly fluorescent material which is used for the estimation of catechol amines in biological fluids according to a procedure first described by Weil-Malherbe and Bone[1] and slightly modified by a number of other workers.

We found that the presence of metallic ions, even in traces, greatly influences the intensity of fluorescence obtained by this reaction. Among the salts that possess such a marked catalytic action are chiefly aluminium chloride (or acetate) and copper sulphate, although Erne and Canbäck[2] have utilized ammonium molybdate for the same purpose. Ferric chloride, on the other hand, appears to decrease the fluorescence of epinephrine while copper sulphate decreases that of norepinephrine.

In the light of these findings, it is more than probable that the presence of aluminium salts in the eluate should be responsible, at least in part, for the increase of fluorescence observed when ethylene diamine is allowed to react with epinephrine dissolved in aqueous acetic acid solutions that have passed through an alumina column, as compared with solutions in pure acetic acid[3,4]. 10 ml. of acetic acid solution that had been passed through a column of 0·7 gm. of alumina prepared according to Weil-Malherbe and Bone were found to contain about 10 μgm. Al+++. The increase of fluorescence under such conditions was about 30 per cent. The addition of 10 μgm. Al+++ (in the form of acetate or chloride) to pure acetic acid increased the fluorescence by 17 per cent. The difference, however, could be explained by the presence of other impurities in alumina. Spectrographic analysis of one sample of purified product (Brickman and Co., suitable for chromatographic adsorption) revealed the presence of minute amounts of copper, iron, gallium and silicium. The influence of these elements on this reaction is under investigation.

A Suggested Revision of Nomenclature—Angiotensin

THE vasoactive peptide resulting from the action of renin on an alpha-globulin was discovered by two groups of investigators with the result that it received two trivial names, angiotonin and hypertensin. Synthesis of the octapeptide has now confirmed the identity of this peptide and justifies dropping the double nomenclature. We propose the simplified name, angiotensin, and its derivatives angiotensinase and angiotensinogen. Angiotensin is a hybrid word but does, we think, have the advantage of being easy to pronounce even with a variety of accents, is euphonious, and is understandable despite the most recalcitrant microphone.

Allelomorphism and the Chemical Differences of the Human Hæmoglobins *A*, *S* and *C*

IN previous communications on this subject, one of us[1,2] reported that normal human hæmoglobin (*A*) and sickle-cell hæmoglobin (*S*) differ in only one out of nearly 300 amino-acids in the half-molecule, and that this is the only demonstrable difference in primary chemical structure. We now wish to report on a similar investigation into the structure of another abnormal human hæmoglobin—that of hæmoglobin *C* disease.

The protein was obtained from individuals known to be homozygous for the hæmoglobin *C* gene. It was first denatured by heat and then digested with trypsin, and the resulting mixture of peptides was analysed by the two-dimensional combination of paper electrophoresis and paper chromatography called 'fingerprinting'[1,2]. The trypsin-resistant 'core' of hæmoglobin *C* was treated with hydrochloric acid–acetone to remove the hæm group. It was then made completely soluble by digestion with chymotrypsin, resulting in a second mixture of peptides. Further examination followed, both by fingerprinting and by more detailed paper chromatography and electrophoresis of groups of peptides from those parts of the fingerprints where the resolution had not been good enough.

When fingerprints of both the chymotryptic and tryptic digests were compared with those of hæmoglobins *A* or *S*, all the peptides of the normal protein were found in their correct positions with the exception of one, which had disappeared. Its place was taken by two peptides in new positions (Fig. 1). The missing peptide is No. 4, the same one which carries the difference between hæmoglobins *A* and *S*. Therefore it is clear that the identical portion of the hæmoglobin *A* molecule is involved in the change to hæmoglobin *C*. Moreover this appears to be the only change, since all the other peptides in the tryptic fingerprint had amino-acid compositions indistinguishable from those of their hæmoglobin *A*, or *S*, counterparts. The peptides of the 'core' still remain to be analysed.

The two new hæmoglobin *C* peptides, called 4*a* and 4*b*, were isolated from tryptic digests by eluting appropriate peptide bands obtained by paper electrophoresis[3], at pH 6·4 at 20 V./cm.; this was followed by a second purification using cooled paper electrophoresis at pH 3·6[3] and 35 V./cm. The amino-acid composition and the N-terminal amino-acid of each peptide were determined qualitatively using the methods previously described[2]. The sequence of amino-acids was found by partial acid hydrolysis and end-group analysis[4] of the products.

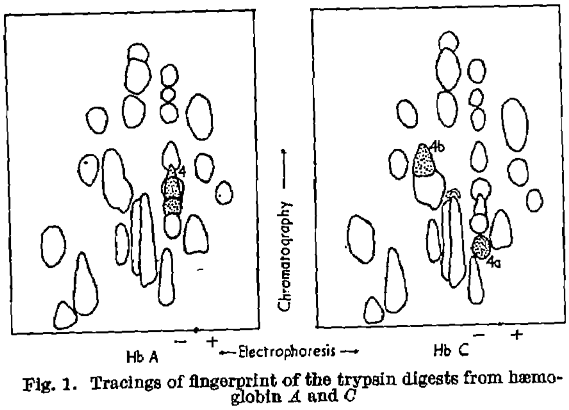

Fig. 1. Tracings of fingerprint of the trypsin digests from hæmoglobin *A* and *C*

Table 1. STRUCTURE OF THE HÆMOGLOBIN *A* AND *S* NO. 4 PEPTIDES AND THE HÆMOGLOBIN *C* NOS. 4*a* AND 4*b* PEPTIDES

(His = histidyl-, Val = valyl-, Leu = leucyl-, Thr = threonyl-, Pro = prolyl-, Glu = glutamyl-, Lys = lysine).

Hæmoglobin *A* . . .	$\uparrow\ \overset{++}{\text{His}}\text{–Val–Leu–Leu–Thr–Pro–}\overset{-}{\mathit{Glu}}\text{–}\overset{-}{\text{Glu}}\text{–}\overset{+-}{\text{Lys}}\ \uparrow\ \ldots$
Hæmoglobin *S* . . .	$\uparrow\ \overset{++}{\text{His}}\text{—Val—Leu—Leu—Thr—Pro—}\mathit{Val}\text{—}\overset{-}{\text{Glu}}\text{—}\overset{+-}{\text{Lys}}\ \uparrow\ \ldots$
Hæmoglobin *C* . . .	$\uparrow\ \overset{++}{\text{His}}\text{–Val–Leu–Leu–Thr–Pro–}\overset{+-}{\mathit{Lys}}\ \uparrow\ \overset{+-}{\text{Glu}}\text{–}\overset{+-}{\text{Lys}}\ \uparrow\ \ldots$

The amino-acid sequences of the No. 4*a* and 4*b* peptides from hæmoglobin *C* are given in the last line of Table 1. Together they add up to the sequence of amino-acids found in the normal No. 4 peptide with the exception of the first glutamic acid residue, which is replaced by lysine. The splitting of the No. 4 peptide into two components during trypsin digestion is now explained, since the new lysine residue constitutes an additional trypsin-sensitive bond. On the basis of these findings we conclude that hæmoglobin *C* differs from hæmoglobin *A* and *S* by only a single amino-acid residue out of nearly 300 in the half-molecule. Moreover, the same glutamic acid residue of hæmoglobin *A* which was changed to valine in hæmoglobin *S* is now replaced by lysine in hæmoglobin *C*. This change from an acidic to a basic amino-acid, involving the loss of two net negative charges per half-molecule, is in agreement with the observed electrophoretic behaviour of hæmoglobin *C*[5].

These results have interesting genetic implications. They are the first steps in a search for a correlation between the linear fine structure of a gene such as that determined recently by Benzer[7] and Pontecorvo[8], and the linear structure of the polypeptide chain of the protein the synthesis of which that gene controls.

The gene mutations which cause the production of the abnormal hæmoglobins *S* and *C* are inherited in a Mendelian manner through nuclear genes[9-11]. Hæmoglobin *C* provides a second example, after hæmoglobin *S*, of the effect exerted by a mutation of this kind on the protein which the gene produces. In both cases the effect is small, since only one out of nearly 300 amino-acids has been altered. We would assume that there have been small alterations in corresponding places on the gene. Hæmoglobin *C* and *S* are most probably independent examples of the same phenomenon, since there is no reason for believing that the two mutations did not arise independently. The fact that both abnormalities occur with high frequency and alter the same amino-acid might well be an accident of natural selection and not an indication of a high mutation-rate at this one particular locus.

Our results also shed light on the position of these two mutations on the hæmoglobin gene or genes. Genetic evidence[9-11] shows that the hæmoglobin *S* and *C* mutations are allelic or occur at linked sites; but the statistical evidence is not sufficiently strong to distinguish between these two possibilities. If we assume a direct relationship between the internal (linear) structure of the gene, and the linear arrangement of the amino-acid residues in the hæmoglobin molecule, then the finding that the same amino-acid residue, glutamic acid, is altered in both mutations implies that they are indeed allelic mutations and occupy the same site on the gene. Thus if these ideas are correct the chemical investigation of proteins such as the human hæmoglobins can provide a powerful, though indirect, tool to help the geneticist in mapping the positions on the gene where certain mutations occur.

In order to obtain sufficient statistical data and a sufficient number of mutants, such a programme must eventually turn to proteins from micro-organisms. However, it is hoped that the abnormal human hæmoglobins will provide a few more useful examples of the effects of gene mutations on protein structure.

We are very grateful to Dr. H. Lehmann, London, Dr. H. A. Itano, Bethesda, and Dr. I. H. Scheinberg, New York, for generous samples of hæmoglobin *C*. We would also like to thank them and Drs. M. F. Perutz and F. H. C. Crick, Cambridge, and Prof. J. V. Neel, Ann Arbor, for many stimulating discussions.

One of us (J. A. H.) is grateful to the Medical Research Council for a scholarship.

Protection against Death due to Ozone Poisoning

In a research programme on the physiological effects of ozone, an attempt was made to determine the mechanism of ozone poisoning by studying chemical protection before exposure. Swiss albino mice were treated by intraperitoneal injections of the test chemical followed by exposure for 3 hr. to a concentration of 8–25 p.p.m. of ozone. This ozone concentration caused death in 10–80 per cent of the animals[1]. Usually 10 control (no prior treatment) animals and 10 treated animals were exposed together in a large glass chamber 12·5 in. × 30 in. × 16 in. to ozone generated by a water-cooled corona discharge type of ozonizer. The results of these experiments are recorded in Table 1.

Since death due to ozone poisoning is accompanied by considerable œdematous fluid in the respiratory system[2], atropine sulphate was tested as a possible protective agent, for it is widely used in surgery to minimize bronchial and nasal secretion. It was successful in preventing death in some of the mice exposed to ozone. Whether this protection is due to the blockage of the response of effector cells to stimulation of postganglionic cholinergic fibres is unknown. The role of the nervous system in pulmonary œdema is not clear. However, Balagot, Reyes and Sadove[3] believe that the autonomic nervous system is implicated. Sarnoff and Sarnoff[4] report that blockade of the sympathetic impulses to systemic vessels lowers pulmonary blood volume and pressure. Avaido and Schmidt[5] present evidence of chemoreceptors in the lungs, with a possible implication in œdema.

The success of the atropine sulphate, a cholinergic blocking drug, in affording some protection against ozone poisoning may be explained by reduction of œdema via the nervous system. However, hexamethonium chloride (Table 1), a ganglionic blocking drug, did not protect mice from death induced by ozone. The ganglion-blocking agents prevent the initiation of postganglionic impulses at the ganglia, while atropine prevents the action of postganglionic impulses upon smooth muscles or glands.

Several reducing substances were tested to determine whether they would protect mice against death from ozone. Since ozone is a powerful oxidizing agent, there is a good possibility that damage to the respiratory system is due to the formation of free radicals and peroxides. Thus a reducing agent should aid animals to survive an exposure to ozone, provided that an intraperitoneally injected reducing substance would be carried as a reducing agent in the blood stream to the respiratory system. Cole *et al.*[6] found that sodium nitrite injected intraperitoneally afforded some protection against death due to radiation.

Table 1. Effects of Various Agents Injected into Mice in Protection against Death from 8–25 p.p.m. of Ozone for 3 hr.

Agent	Dosage/mouse		Treated mice			Control mice			X^2*
	(mgm.)	(ml.)	Total	Survived (*a*)	Dead (*b*)	Total	Survived (*a*)	Dead (*b*)	
Atropine sulphate	0·00325	0·1	118	88	30	119	74	45	4·2
Hexamethonium chloride ('Hexameton', Burroughs Welcome)	0·125	0·1	110	70	40	111	63	48	0·59
Sodium thiosulphate (*p*H 7·7, sodium hydroxide)	40	0·5	71	55	16	70	42	28	4·62
Ascorbic acid (sodium ascorbate, Barry Laboratories)	20	0·2	90	70	20	90	56	34	5·18
Glutathione (*p*H 8·0, sodium hydroxide)	65·8	1·0	20	12	8	20	11	9	0·0
Sodium nitrite (*p*H 7·2, sodium hydroxide)	2·5	0·5	20	7	14	20	18	2	0·0
Sodium nitrite (*p*H 7·2, sodium hydroxide)	1·75	0·25	67	35	32	68	35	33	0·0
p-Aminopropiophenone (in 2 parts 100 per cent ethyl alcohol and 8 parts propylene glycol)	1·0	0·1	40	11	29	40	22	18	0·0

* G. S. Snedecor, "Statistical Methods", p. 19 (Iowa State College Press, Ames, Iowa, 1940).

* $X^2 = \dfrac{(ad - bc)^2\,(a + b + c + d)}{(a + c)\,(b + d)\,(a + b)\,(c + d)}$

If the value of X^2 is 3·84, there is more than a 95 per cent chance that the treated population is different from the control.

With this in mind, other reducing agents were used. Both sodium thiosulphate and ascorbic acid (Table 1) protected mice against death by ozone poisoning. These compounds may react with ozone before it has a chance to come into contact with lung tissue, or afford protection by decreasing capillary permeability in the lungs, and by sustaining the alveolar capillary cells during conditions of anoxia. Sodium nitrite at 2·5 mgm. per mouse (Table 1) did not protect mice but made ozone more toxic. At a level of 1·75 mgm. per mouse there was no effect on mortality due to ozone. The apparent increase in death-rate of mice injected with 2·5 mgm. of sodium nitrite can be explained by the induction of methæmoglobinæmia[7] by this compound. A sharp reduction in available hæmoglobin would handicap an animal severely injured by ozone and would hasten death due to asphyxiation.

Glutathione and *p*-aminopropiophenone[9], which have had some success in protection against death due to radiation, were not successful in protecting against death induced by ozone poisoning. Gerschmann and colleagues[10] pointed out the similarities between oxygen poisoning and injury due to radiation and found that glutathione protected against oxygen poisoning. It appears that compounds which protect against death by radiation and oxygen poisoning are not effective against ozone poisoning. The difference in protection is due to the fact that damage in ozone poisoning appears to be limited to the respiratory tract only, whereas in radiation and oxygen poisoning the whole body is involved.

This study was supported by funds provided under Contract *AF* 18(600)-944 with the U.S.A.F. School of Aviation Medicine, Randolph Field, Texas.

Isolation of β-Sitosterol-D-Glucoside from Groundnut Phospholipids

NATURALLY occurring sterol glycosides (sterolins) were first characterized in 1913 by Power and Salway[1], since which time these compounds have been isolated from a variety of plant materials[2,3].

In the course of experiments on the lipids of groundnuts, a sterol glycoside has been isolated from a crude phospholipid fraction and has been identified as β-sitosterol-D-glucoside.

The initial phospholipid was produced on an industrial scale; in order to remove small amounts of triglyceride the material was washed several times with three times its weight of acetone, dissolved in ether and reprecipitated with acetone. The precipitate was filtered off on a Buchner funnel and final traces of solvent then removed *in vacuo*.

129 gm. of this material was ground with about 300 gm. of anhydrous sodium sulphate and the mixture extracted with acetone in a large Soxhlet extractor for 22 hr. The acetone extract on cooling gave a yellow waxy solid which after washing with ether yielded a white powder, insoluble in most of the usual solvents but soluble in pyridine. Further quantities of this material were obtained by concentrating the acetone extract, and in all 2·3 gm. (1·8 per cent of the crude phospholipid) was obtained.

The product was recrystallized from pyridine–ethanol as a loose white solid giving positive Lieberman–Burchard and Molisch tests, m.p. 290–292° (dec.) and $[\alpha]_D^{20} - 45{\cdot}7$. These values correspond with those reported by other workers[4,5] for β-sitosterol-D-glucoside, and the identity of the solid was confirmed by the melting points and specific rotations of the acetyl and benzoyl derivatives, and by identification of the sterol and sugar components following hydrolysis of the glycoside by the method of Thornton and co-workers[6]. Chromatographic analysis showed glucose to be the only carbohydrate component in the water-soluble portion of the hydrolysis products, and the presence of glucose was confirmed by osazone formation. Recrystallization of the ether-soluble hydrolysis products yielded a sterol, m.p. 135–136°, $[\alpha]_D^{20} - 37{\cdot}17$, in 75 per cent yield. The acetate (m.p. 126° $[\alpha]_D^{20} - 43{\cdot}01$) and benzoate (m.p. 142–143°, $[\alpha]_D^{20} - 15{\cdot}1$) correspond to β-sitosterol derivatives.

In further experiments the crude phospholipid was fractionated with alcohol; the alcohol-insoluble material corresponded to 75 per cent of the initial phospholipid and contained 87·5 per cent of the total sterol glycoside.

Thanks are due to the Nuffield Foundation for their support of this work and to Messrs. J. Bibby and Sons for the supply of phospholipid.

Site of Catabolism of Serum Albumin

THE relative importance of the liver, kidneys and intestines for the catabolism of serum albumin has been examined in Swiss albino mice, 5–6 weeks of age. Mouse serum albumin and human serum albumin were labelled with iodine-131 as described elsewhere[1] and given to the mice intravenously, about 0·5 μc. or 5–15 μgm. iodoalbumin per mouse. The biological half-lives of the radioiodinated albumins were determined by one or more of three methods: (1) the living whole mouse was counted at intervals in a crystal scintillator; (2) pooled serum was obtained by exsanguination of two or three mice at a time

Table 1. Half-lives of Iodinated Albumins in Mice

Conditions (see text)	Half-lives during first 24 hr.* (days)
Normal diet: unoperated or sham-operated	0·7
Partial hepatectomy (40 per cent)	1·7
'Thorotrast' (0·6 ml.)	2·2
Indian ink (0·1 ml.)	1·8
Starvation	1·1
Sham operation and starvation	1·2
Bilateral ureteral obstruction	1·4–1·7
Bilateral nephrectomy	1·4
Intestinal resection	0·7

* Average values for at least 15 animals per group, excepting nephrectomy, which included eight animals. Data on individual animals varied by less than 20 per cent from the average.

from a given group and the protein-bound radioactivity of the serum determined; (3) protein-bound radioactivity in the individual whole mouse of a given group was estimated after homogenization of the animal in 10 per cent trichloracetic acid. All animals were given sodium iodide in their drinking water throughout the period of an experiment. Surgical operations were performed under ether anæsthesia. In these experiments, iodinated human albumin behaved *in vivo* as did iodinated mouse albumin; detectable antibodies to human serum albumin were not formed during the periods of study chosen.

The half-life of serum albumin in normal mice was found to be about 0·7 day (Table 1) (this value has been averaged with additional data obtained by G. Terres and W. Wolins and is based on more than 50 animals). Since the mice in several experiments were anorexic, the half-life of albumin in mice not given food was determined and found to be about 1·1 days. Sham operations were also performed in which the peritoneal cavity was opened and the intestines lifted out and replaced. The half-life of albumin in sham-operated mice with or without food was similar to that obtained for unoperated mice on the same diet (Table 1).

The ureters were obstructed bilaterally in a group of mice approximately 3 hr. prior to injecting labelled albumin by applying a gold clamp at the base of the bladder. These animals were not given food. The half-life of serum albumin under these conditions was found to vary from 1·4 to 1·7 days in different groups of mice; these values should be compared with 1·2 days for the sham-operated controls. The half-life of albumin in mice that were bilaterally nephrectomized was 1·4 days.

Removal of both large and small intestines appeared to accelerate the catabolism of iodinated albumin, since the half-life was only 0·7 days as compared with 1·2 days for starved controls (Table 1).

Removal of 40 per cent of the liver resulted in a marked decrease in the catabolism of albumin (Table 1). During the first day after the operation, the half-life was found to be 1·7 days. During the second day, the half-life of albumin was 0·9 days. Five days after the operation, the half-life of albumin was normal and post-mortem examination revealed that the liver had regenerated to normal size. The hepatectomized mice were eating soon after the operation, and the half-life value found is to be compared with that for mice on a normal diet. Removal of approximately 40 per cent of the liver decreased the fractional rate of catabolism by about 50 per cent. Similarly, removal of about 20 per cent of the liver decreased the fractional rate of catabolism about 20 per cent.

An attempt was made to determine the relative influence of the hepatic cells and the Kupffer cells on albumin catabolism. 'Thorotrast', which is a 24–26 per cent suspension of thorium dioxide, and indian ink are known to block the reticulo-endothelial system. Consequently, 0·05–0·1 ml. of indian ink or 0·2–0·6 ml. of 'Thorotrast' was given to mice intravenously, followed 1 hr. later by iodinated albumin; there was a profound inhibition of albumin catabolism (Table 1). Large doses of 'Thorotrast' reduced the catabolism of iodinated albumin to an extent even greater than that observed in mice with 40 per cent of their livers removed.

It would appear from these results that the liver and kidneys in mice play significant parts in the catabolism of albumin. The liver would seem to have the greater importance, since removal of only 40 per cent of the liver was more effective than complete nephrectomy. At the cellular level, the experiments with indian ink and 'Thorotrast' strongly implicate the reticulo-endothelial system of the liver in this catabolism, although a possible role of the hepatic cells cannot be excluded.

Effects of Pituitary Hormones and Cortisone upon Liver Regeneration in the Hypophysectomized Rat

The finding that growth hormone increased the rate of mitosis and nucleic acid synthesis in rat regenerating liver[1], suggested that this hormone might play an important part in liver regeneration following partial hepatectomy. To test this hypothesis it was necessary to study the effect of hormones upon liver regeneration after removal of the pituitary.

Three series of experiments were performed on rats subjected to partial hepatectomy 7–28 days after hypophysectomy. It is believed that the use of this preparation has not been previously described; full details will be reported later (by J. T. H.). Rats were killed at two hourly intervals from 27 hr. to 50 hr. after partial hepatectomy and mitotic counts were made on the livers.

The first series of saline-injected controls (80 rats) 14–21 days after hypophysectomy showed that liver regeneration can occur in the absence of the pituitary, but is delayed. Normal rats show a peak of regeneration of about 40 mitoses/1,000 cells at about 28½ hr. after partial hepatectomy[2]; but in hypophysectomized rats the peak is at 38–45 hr. and is only 20–30 mitoses/1,000 cells.

A second series of 80 hypophysectomized rats were given hormone replacement at hepatectomy and during liver regeneration. Six groups were used, given respectively: growth hormone only, crude pituitary extract only, cortisone only, growth hormone +

cortisone, crude pituitary extract + cortisone, and a control group injected with saline. Giving growth hormone + cortisone or crude pituitary extract + cortisone resulted in an increase of the height of the mitotic peak with little alteration of the time at which maximum regeneration occurred. Results from growth hormone and crude pituitary extract alone were equivocal.

In the group treated with cortisone only, a consistent and characteristic cytoplasmic and nuclear degeneration was noted (by D. B. C., who did mitotic counts on these two first series of rats). The cells undergoing degeneration appeared to follow a series of changes, beginning with a hyaline droplet type of degeneration of the cytoplasm, followed by vacuolation of the nucleus and extrusion of the nucleolus. The nucleus in the more degenerate cells became pyknotic and finally broke into fragments. These changes were much more marked than the cytoplasmic vacuolation and nuclear displacement reported in liver cells of mice treated with cortisone[3].

A third series of experiments was then begun (by J. T. H.) to test the hypothesis suggested by the work of Bullough (recently reviewed[4]), that the nutritional state of the liver at hepatectomy greatly influenced the subsequent regeneration, and that some conditioning of the cell by hormone activity was essential for normal regeneration.

Injections of the same combinations of hormones were therefore given three days prior to hepatectomy and during the period of regeneration.

65 hypophysectomized rats have so far been examined, and in all those receiving cortisone only (2 mgm./100 gm. rat twice daily) no mitoses were found at any regeneration time from 27 to 60 hr. (Cortisone inhibition of liver regeneration in the mouse, with intact pituitary, has been reported[3].) Glycogen content of the liver was high at hepatectomy and was still high at post-mortem, suggesting that glycogen utilization was small in the cortisone-treated rat. Except in very small doses, growth hormone or crude pituitary extract given alone was toxic to hypophysectomized-partially hepatectomized rats, many animals dying through hypoglycæmia and ketosis. Such material as was available indicated that mitotic rates were low (5–20 mitoses/1,000), and that glycogen accumulation was also low. Further work is in progress.

When growth hormone or crude pituitary extract was given with cortisone the whole picture changed; the highly pyknotic and degenerating nucleus gave place to more normal appearances with clear mitotic figures. When the dose of growth hormone was in the correct proportion to the dose of cortisone high mitotic counts were seen. High accumulation and utilization of glycogen also occurred. Thus, 1·5 mgm. growth hormone or 0·6 ml. crude pituitary extract (100 gm. rat twice daily) with 2 mgm. cortisone gave high counts of 45–60 mitoses/1,000 cells. Reducing the dosage of either to an eighth and keeping the cortisone dose at 2 mgm. gave low mitotic counts and slight signs of cytoplasmic and nuclear degeneration.

Thus growth hormone prevented the inhibition of mitosis and the nuclear degeneration produced by cortisone. With cortisone alone there was nuclear degeneration in spite of accumulation of glycogen in the cytoplasm. Failure to regenerate deoxyribonucleic acid has also been reported after cortisone administration to the intact mouse[3]. These facts suggest the possibility of a metabolic block set up by cortisone between the cytoplasm and the nucleus; this block is removed or neutralized by growth hormone. Conversely, this work supports that of many workers showing growth hormone to diminish glucose uptake by the cell in hypophysectomized animals, and in particular is direct support for the view that growth hormone requires the co-operation of adrenal corticoids for normal carbohydrate metabolism[5].

In physiological conditions it may well be that growth hormone is the more constant basal secretion allowing nuclear activity and this is modified by hour-to-hour variation in adrenal corticoid output. When cortisone is excluded there are indications that glycogen utilization is related to mitotic rate. It is possible that the autonomy of neoplastic cells is in part a loss of response to corticoid inhibition, and the relation between these two possibilities is being examined. In those cases of inoperable cancer which have been treated by hypophysectomy and maintained on cortisone, these studies suggest that part of the beneficial therapeutic response may be due to a direct effect of cortisone on the dividing cancer cells, probably accentuated by absence of pituitary growth hormone.

We are grateful to Prof. J. S. Mitchell for his advice and encouragement, and to Prof. F. G. Young for his generous gifts of growth hormone and crude pituitary extract. One of us (J. T. H.) acknowledges a Medical Research Council grant, and the other (D. B. C.) a British Empire Cancer Campaign research fellowship.

Fine Structure of the Alveolar Wall of the Lung

SINCE electron microscope techniques have been applied to histology, several workers have confirmed that the blood–air barrier of the lung consists of a capillary endothelium, a basement membrane and an uninterrupted alveolar endothelium. The permeability of this three-layered wall is explained, in the classical physiological literature, solely by a passive physicochemical mechanism.

Palade[1] was the first to observe with the electron microscope that the fine structure of the capillary wall was much more intricate than had been previously assumed. He saw invaginations of the plasma membrane which are pinched off to form small vesicles of 500–750 A. diameter. It seems likely that they move across the endothelial cytoplasm and approach the opposite plasma membrane. Palade[2] himself believes that substances from the capillary lumen can thus be actively and selectively incorporated into the endothelial cytoplasm. This mechanism, formerly called pinocytosis, appeared to depend, so far as the capillary endothelium is concerned, upon the requirements of the surrounding medium.

Quite recently, Moore and Ruska[3] described capillary endothelia of the mammalian heart and suggested that the plasma membrane vesiculation mechanism, described by Palade[1,2], is a prevalent process of active and selective transport of substances across the cytoplasm and cell membranes. They call this exchange mechanism 'cytopempsis'.

Nevertheless, Moore and Ruska[3] suppose that in pulmonary capillaries physicochemical permeability is enough to maintain transport through the blood-air barrier, because their layers are extremely thin. Therefore, they did not expect to find morphological images of cytopempsis at this level.

We did not consider the negative results convincing proof of the absence of cytopempsis, therefore we have re-investigated the fine structure of this three-layered wall.

The present observations are based upon techniques recently described[4] and were made on lungs of adult albino mice.

Structural details assumed to be concerned in cytopempsis are shown in the alveolar wall in Figs. 1 and 2. There are many small vesicles of 500–700 A. diameter in the endothelial cytoplasm. They are usually spherical, consisting of a relatively light portion surrounded by a thin dark membrane. The exterior and the interior plasma membrane invaginations show in several places. Some of the spherules approach these invaginations and often fuse with the bottom of them.

The thin epithelial lining of the alveolar cells surrounding the capillary vessels has a structure remarkably like that of the endothelial cytoplasm. There are also small vesicles of about the same size as those described in the endothelium. Invaginations of exterior and interior plasma membranes can easily be identified.

Finally, numerous small cell-membrane infoldings, similar to those belonging to the exterior cell membranes, are found in contact with the alveolar basement membrane. Some of these in profile are closed, whereas others appear to be partially or completely open at the level of the basement membrane.

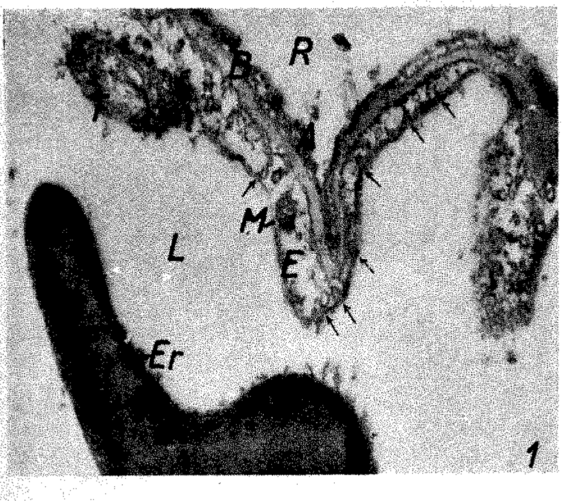

Fig. 1. Blood-air barrier in mouse lung. A large capillary lumen (*L*) is visible below, with a red blood cell (*Er*) and a thrombocyte (*T*) in close contact with the endothelial lining. Vesicles, which are bounded by dense membranes, appear throughout the entire endothelial cytoplasm (*E*), often in connexion with small invaginations (→) of the exterior plasma membrane. A mitochondrial profile (*M*) can be recognized in the endothelial cytoplasm. The alveolar lumen (*R*) is bounded by the alveolar epithelium (*A*). The basement membrane (*B*) is represented by a layer between endothelium (*E*) and epithelium (*A*). (× 25,000)

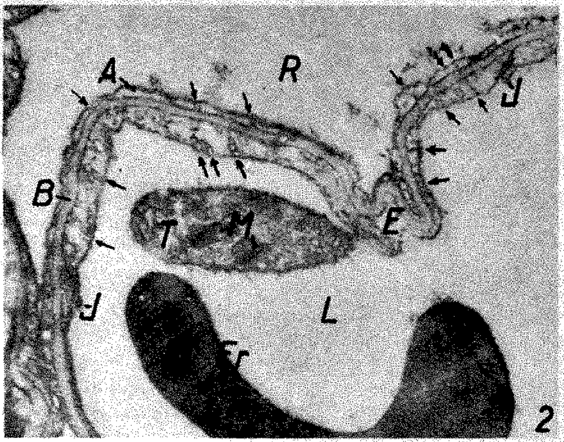

Fig. 2. Another portion of the blood-air barrier in mouse lung, showing numerous small vesicles in the capillary endothelial (*E*) and the alveolar epithelial (*A*) cytoplasm, and invaginations (→) of the exterior and interior plasma membranes. The vesicles are often associated with the bottom of an infolding of the cell membrane. Two endothelial junctions (*J*) are visible. (× 26,000)

Schulz[5] described vesicles of 500–1000 A. diameter within the alveolar and endothelial cytoplasm of the blood-air barrier in lungs of mammals submitted to artificial lung-œdema. He is convinced that these structural details must be due to the experimental œdema produced. Obviously, he did not know that Palade[3] had found the same vesicles three years before in quite normal circumstances, within the capillary endothelium of the mammalian heart. Moreover, Schulz did not use controls, an omission which makes his conclusion less convincing. The electron microscope literature is still too small to distinguish between the so-called 'normal fine structures' and artefacts.

On the basis of these results, we believe that the idea that transmission of substances through the alveolar wall occurs only by passive diffusion should be further studied. The occurrence of cytopempsis within the normal alveolar wall is important evidence in favour of both alveolar epithelial and capillary endothelial cells being active and selective in the exchange of substances in the lung.

Inability of Hydrogen Peroxide to influence the Survival-Time of Rats bearing *RD3* Sarcoma and the Walker Carcinoma

It has recently been claimed that orally administered hydrogen peroxide (0·45 per cent by weight) causes regression of the transplantable Walker carcinoma in rats[1], and it was also claimed that two of four cancerous patients benefited from this treatment. It seemed to us that orally administered hydrogen peroxide was unlikely to survive passage through the gut, but an impurity or added stabilizer which was to some extent carcinolytic might be present. In order to try out this likelihood the experiments described below were made. We found that the survival-times for rats bearing either Walker carcinoma or *RD*3 sarcoma were almost identical in the animals treated with hydrogen peroxide and those fed tap-water. There was, however, some possible difference affecting the rate of tumour growth in the two groups (possibly slower in the animals treated with hydrogen peroxide) and an explanation of that phenomenon is given in the discussion below.

The *RD*3 sarcoma used in these experiments was originally induced by 1 : 2 : 5 : 6-dibenzanthracene injection into the right flank of an inbred strain of albino rats. The Walker carcinoma was obtained from the Department of Experimental Pathology, University of Leeds.

Animals used in these experiments were inoculated subcutaneously in the right flank with 0·2 ml. of a thick pasty suspension of tumour mince under strict aseptic conditions. (Walker carcinoma or *RD*3 sarcoma.)

The diet used throughout these experiments was diet 86 purchased from the North-Eastern Agricultural Co-operative Society Ltd., Bannermill Place, Aberdeen. All animals were fed *ad lib.* and were housed in separating cages and weighed individually twice a week.

The commercial concentrated aqueous solution of hydrogen peroxide (Laporte Chemicals Ltd., Luton) was diluted to give a final concentration of 0·45 per cent (by wt. : the suggested optimum of Holman[1]). This solution was fed *ad lib.* to the experimental groups of animals. The solution was replaced every 3 days and an analysis of the hydrogen peroxide concentration showed that no deterioration had occurred.

Experiment 1. Male rats were inoculated with *RD*3 sarcoma in the right flank. At the end of 5 days, 66 animals showing fairly uniform palpable tumour nodules measuring approximately 1·0 cm. in diameter were selected and divided into two groups. Group *A* received 0·45 per cent hydrogen peroxide from then on until the end of the experiment while the control group *B* received ordinary tap-water. Table 1 summarizes the results obtained. There was no statistically significant difference between the survival times and the final tumour weights in these groups.

Table 1. THE EFFECT OF 0·45 PER CENT HYDROGEN PEROXIDE (AS A SUBSTITUTE FOR DRINKING WATER) ON THE GROWTH OF TRANSPLANTED *RD*3 SARCOMA, HOST TISSUES, AND ON SURVIVAL-TIME IN THE RAT

(Treatment started 5 days after transplantation of the tumour)

	Exp. 2		Exp. 3.	
	Fed hydrogen peroxide	Fed tap-water	Fed hydrogen peroxide	Fed tap-water
No. of rats	14	15	18	17
Survival-time (days)	25·8± 8·5	26·7± 4·0	20·1± 3·4	21·9± 4·2
Final tumour wt. (gm.)	73·4±30·7	97·8±60·0	40·1±11·4	58·5±12·9
Initial host wt. (gm.)	279·0±26·5	278·0±31·2	240·0±11·6	240·0±12·8
Final host wt. (gm.)	232·0±43·5	300·0±20·0	173·0±39·2	248·0±35·9

Experiment 2. Male rats were inoculated with the Walker carcinoma. At the end of 5 days, 29 animals showing fairly uniform palpable tumour nodules measuring about 1·0 cm. diameter were selected and divided into two groups and treated in the same way as animals in exp. 1. Table 2 summarizes the results obtained. Once again there was no statistically significant difference between the survival times and the final tumour weights in these groups, although as in exp. 1 there was a lower final body-weight and tumour weight in the experimental animals.

Experiment 3. This is a repeat of exp. 2 ; but, as in this experiment the Walker carcinoma grew at a faster rate than that in exp. 2, the results were considered separately from those in exp. 2.

Once again hydrogen peroxide failed to prolong significantly the survival rate of the treated animals. The tumours in group *A* were, however, significantly smaller than those in group *B* : the final host weight of group *A* was less than that of group *B*, but not significantly so.

In view of the persistent tendency to a smaller body-weight in animals receiving hydrogen peroxide in all our experiments, it was decided to study the effect of hydrogen peroxide on the food intake and body weight of normal animals.

Experiment 4. Forty-eight rats were divided into two groups. Both groups were fed *ad lib.*, but group *A* (24 rats) received 0·45 per cent hydrogen peroxide instead of the tap-water which group *B* (24 rats) received. The amount of food eaten by each group was estimated by weighing the amount of food given and that left over and wasted. The animals were weighed individually every few days. The initial weight of the control rats was 189 ± 11 gm. (mean and standard deviation) and that of the experimental rats was 190 ± 9 gm. At the end of the experimental period (57 days) the rats in the control group weighed 253 ± 21 gm. and the experimental rats weighed 236 ± 13 gm., showing a significant difference in the rate of growth in the two groups. Group *A* consumed 23·8 kgm. food and group *B* 28·4 kgm.

The results of our experiments fail to confirm the findings of Holman[1]. In common with Green and Westrop[2] we find no evidence to suggest that hydrogen peroxide increases the survival-time of rats bearing the Walker carcinoma.

So far as the effect of hydrogen peroxide on final tumour size is concerned our results are more difficult to interpret. In any experiment designed to reveal inhibition or stimulation of tumour growth the nutritional status of the animals must be taken into consideration (Tannenbaum[3]; Rous[4]; Ghadially and Wiseman[5]), for it is well known that if the animal loses weight tumour growth is likely to be impaired. The results of exp. 4 (above) on non-tumour rats show that hydrogen peroxide diminished food intake and retarded normal growth, and a tendency for animals receiving hydrogen peroxide to show a decrease in carcass weight and somewhat smaller tumours is to be expected.

Spontaneous Crystallization of Amylase from Pancreatic Juice of the Rat

IN the assay of secretin by Love's method[1] in which pancreatic secretion from the fasted rat is collected in calibrated capillary tubes, it was observed that a slight precipitate very occasionally formed in the tube at room temperature. When the secretion was kept at +2° C. a heavy white deposit almost invariably formed within two days or so which consisted of very fine birefringent needles, often in balls, fans, or sheaves (Fig. 1). The difference in ultra-violet absorption of the secretion before and after formation of the deposit (Fig. 2) suggested that the latter might be a protein. Further experiments showed it to be amylase, and it became of interest to compare its properties with those of crystalline pancreatic α-amylase from human[2] and pig[3].

Isolation and recrystallization. The crystals were only sparingly soluble in water and could be washed repeatedly in cold water. They were much more soluble above *p*H 10, and could be recrystallized by suspending in water, adding ammonia to a final concentration of 0·2 *M*, agitating for 15–20 min., and centrifuging; about one-quarter of an equivalent of hydrochloric acid was then added, the slight turbidity was spun down after half an hour, and the tube placed in a closed container with several ml. of dilute sulphuric acid to absorb ammonia, the whole being kept at 2° C. Several days were required for crystallization, and the crystals thus obtained have not yet been larger than those separating spontaneously from crude pancreatic juice.

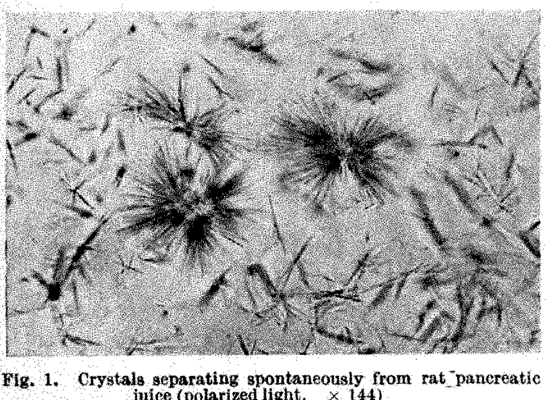

Fig. 1. Crystals separating spontaneously from rat pancreatic juice (polarized light. × 144)

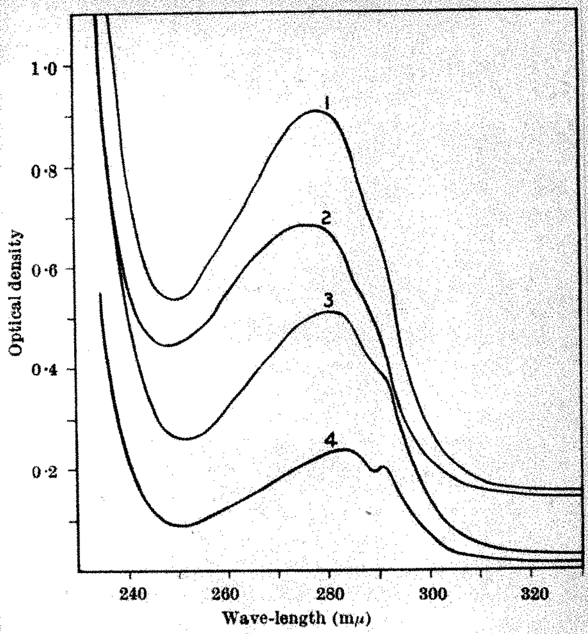

Fig. 2. Ultra-violet absorption (1 cm.) of: (1) pure pooled pancreatic secretion of three rats, collected over a period of 11–12 hr. (with frequent stimulation by secretin) diluted 1 in 40; (2) supernatant from the same after 7 days at 2° C., diluted 1 in 40; (3) recrystallized material, 0·256 mgm./ml., *p*H 7; (4) difference between 1 and 2

Stability. Well-washed crystals suspended in water appeared to retain their activity at 2° C. for many weeks. At 20° C. all activity was destroyed in a few seconds in 0·02 *N* hydrochloric acid; in acetate buffer *p*H 4, about nine-tenths of the original activity remained after 3 hr., and at *p*H 5 there was little or no destruction. In the *p*H range corresponding to 0·1–1·0 *M* ammonia the stability showed a sharp change. Thus, in 1·0 *M* ammonia at 20° C. destruction was virtually complete after 30 min.; in 0·5 and 0·1 *M* ammonia after 3 hr. about 30 per cent and 90 per cent of the original activity remained. A suspension of crystals dried quickly over phosphorus pentoxide and kept over it for two weeks retained only about one-quarter of its original activity.

Solubility. A dense suspension of crystals was distributed among a number of sealed glass capillaries which were gently agitated at the appropriate temperature for varying lengths of time. After centrifuging, the concentration of amylase in the supernatant was estimated in terms of its amylase activity. In water the approximate solubility was: at 2° C., 0·3 mgm./ml.; at 20° C., 1·5 mgm./ml.; at 37° C., 3 mgm./ml.

The crystals still formed spontaneously in the presence of bile or of 'Teepol' (which was sometimes used for ensuring smooth movement of the meniscus in the secretin assay).

Amylolytic activity. This was measured by the method described by Noelting and Bernfeld[4] based on that of Sumner and Howell[5], using British Drug Houses 'Analar' starch as substrate. The potency is expressed in units equivalent to the number of milligrams of maltose liberated by 1 ml. of enzyme solution in 3 min. at 20° C.

Once recrystallized material had a specific activity of about 620 units/mgm. That repeated recrystallization would enhance this considerably seems unlikely since well-washed crude crystals (not recrystallized) had almost the same activity.

Table 1

Origin of amylase	pH range of stability	Activity (maltose units/mgm.)
Pig pancreas*	7– 8·5	630
Human pancreas*	4–11	1,000
Rat pancreatic juice	5–10·5	620

* Based on results summarized by Bernfeld (ref. 6)

Comparison with human and porcine pancreatic amylase. All three enzymes have certain properties in common (ultra-violet absorption spectrum, low solubility, high stability when pure). The porcine and human enzymes differ in their pH stability-range and in activity, and it is interesting that the rat amylase resembles human, rather than porcine, enzyme in the first of these properties, and porcine rather than human enzyme in the second (Table 1).

Serine–Glycine Interconversion in Plant Tissues

THE conversion of serine to glycine in animal tissues was first demonstrated by Shemin[1] by a feeding experiment using serine labelled with nitrogen-15 and carbon-13 in the carboxyl group. The involvement of a folic acid derivative as a co-factor in the reaction was shown both by Kisliuk and Sakami[2] and Blakley[3].

That the interconversion occurred in plant tissues seemed probable in view of labelling data obtained by Tolbert and Cohan[4], who fed 1-^{14}C- or 2-^{14}C-labelled glycollate to wheat and barley leaves and found, in short experiments, that serine and glycine were the only major products labelled. The 2-C atom of glycollate was observed to enter the 3-C atom of serine, presumably glyoxylate formed by oxidation of the glycollate being split by the Sakami reaction to form formate[5], which is known to enter largely into the 3-C atom of serine[6]. Attempts to demonstrate the interconversion in cell-free systems from plants have not previously been successful[4].

This communication reports the occurrence of this interconversion in a cell-free system prepared from turnips. The tissue was homogenized in 2-3 vol. cold 0·2 M potassium phosphate buffer, pH 7·4, in a bottom-drive blender. The suspension was strained through a linen cloth and then centrifuged at 1,000g, for about 5 min. to remove cells and debris. Ammonium sulphate was then added to 80 per cent saturation. The protein was separated by centrifugation and dissolved in about 30 ml. of the same buffer. The solution was dialysed overnight against a flow of 2·5 l. of 0·01 M buffer, pH 7·4. The enzyme preparation was centrifuged at 30,000g for 10 min. before use. All these operations were carried out in a cold-room at 2° C.

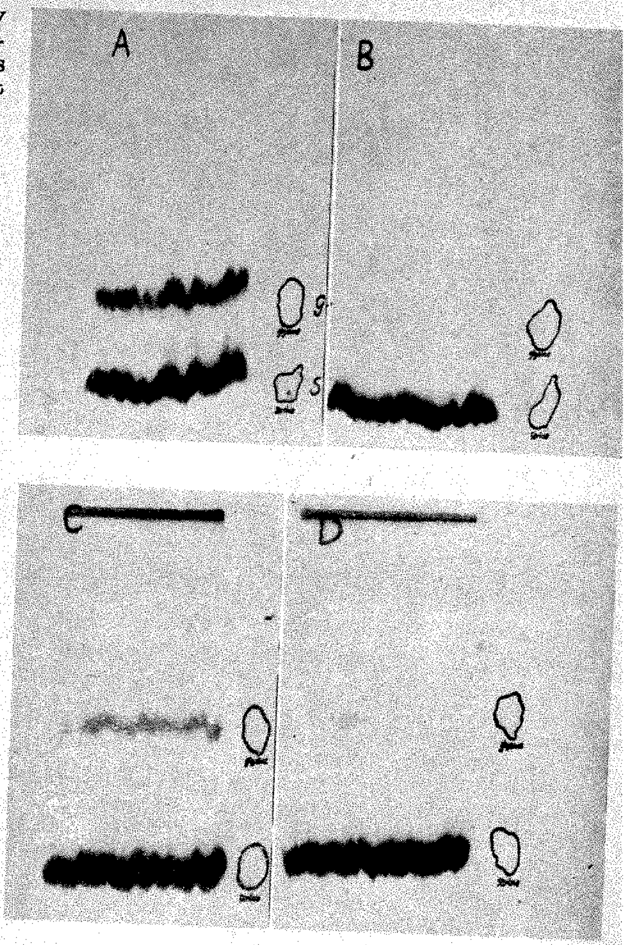

Fig. 1. Radioautographs of chromatograms demonstrating serine–glycine interconversion. *A*, Full system; *B*, ethanol at zero time; *C*, no pyridoxal phosphate; *D*, no tetrahydrofolic acid; *G*, glycine; *S*, serine markers. The full system contained: enzyme, 1 ml.; generally labelled carbon-14 L-serine 8 × 10^4 counts per min.; L-serine carrier to a final concentration of 1 μmole; glycine, 1 μmole; DL-tetrahydrofolic acid approximately 0·33 mM; pyridoxal phosphate, 0·25 mM; Mg^{2+}, 1 μmole. Total volume 1·53 ml. The flasks were gassed with hydrogen and incubated at 37° for 150 min.

The DL-tetrahydrofolic acid solution was prepared by the catalytic hydrogenation of folic acid in neutral aqueous solution[7].

The reaction was stopped by the addition of ethanol to a final concentration of 80 per cent and the protein removed by centrifugation. The supernatants were reduced to dryness on a water-bath, and the contents of the dishes transferred to Whatman No. 1 filter paper in 50 per cent ethanol. The solvent used to run the chromatograms contained acetone (80 parts), triethylamine (5 parts) diluted to 100 with water[8]. The papers were dried and exposed to X-ray paper. The appearance of the latter after development is shown in Fig. 1.

There appears to be an absolute requirement for tetrahydrofolic acid, presumably established by the prolonged dialysis alone; the enzyme had not been treated with 'Dowex-1-Cl'[2]. The reverse reaction has also been demonstrated, starting with glycine generally labelled with carbon-14. The enzyme catalysing this reaction has also been shown to occur in extracts of immature cauliflower.

Further work is in progress on quantitative aspects of this reaction and similar C_1-transferring reactions are being studied.

We are indebted to the Royal Society and the Agricultural Research Council for grants towards the purchase of apparatus and chemicals.

Carbon Dioxide Fixation in Particulate Preparations from Barley Roots

Carboxylation of phosphoenolpyruvate in plant material has been reported by various workers[1-5]. In the present investigation we have observed it in particulate preparations from barley roots. This reaction, coupled with malic dehydrogenase activity in the presence of reduced diphosphopyridine nucleotide, leads to the incorporation of carbon-14 dioxide into malate and other organic acids.

The particles prepared from 6-day old barley roots were separated by centrifuging between 2,000 and 16,000 × *g*. Exposure to labelled potassium bicarbonate was carried out for a period of 1 hr. After acidification to terminate the reaction and removal of the excess carbon-14 dioxide, the medium was centrifuged to give two fractions: the supernatant and the residue. Aliquots of the supernatant and the residue were plated and from these the total carbon-14 dioxide fixation was determined.

Initial experiments in the absence of reduced diphosphopyridine nucleotide and with phosphoenolpyruvate showed a marked stimulation of the carbon dioxide fixation as compared to the fixation with pyruvate. Table 1 shows the fixation obtained in the two systems. Radioautographs of the paper chromatograms of the supernatants from both systems showed that only traces of labelled malate were present. 2,4-Diphenylhydrazones were prepared, and the activity expressed as the percentage of the total carbon-14 fixed gave figures of 80 per cent for the phosphoenolpyruvate and 5 per cent for the pyruvate. Radioautographs of paper chromatograms showed that in both systems labelled oxalacetate and pyruvate were formed, with a large accumulation of labelled oxalacetate in the presence of phosphoenolpyruvate. The results indicated that conditions were limiting for the further metabolism of the labelled oxalacetate.

The presence of added reduced diphosphopyridine nucleotide resulted not only in an increase in the total carbon dioxide fixation, but also in the activity of the ether-soluble fraction, particularly in malate. The organic acids in the supernatant were isolated by ether extraction followed by silica gel chromatography after the method of Bulen *et al.*[6]. Addition of malate increased the total fixation; however, the proportion of activity in the ether-soluble fraction remained the same except in the presence of added reduced diphosphopyridine nucleotide.

Table 1. Carbon-14 Dioxide Fixation in Barley Root Particles with no Added Reduced Diphosphopyridine Nucleotide (Activity as percentage of total carbon-14 added)

Fractions	Supernatant	Residue	Total
Substrate			
1. Pyruvate (sodium salt)	1·1	1·0	2·1
2. Phosphoenolpyruvate (cyclohexamine salt)	12·0	2·6	14·6

Reaction mixture: 1 ml. particles containing 1·30 mgm. nitrogen, 60 μmoles substrate, 4·5 μmoles magnesium chloride, 0·6 μmoles manganese chloride, 90 μmoles phosphate buffer (1) *p*H 5·6, (2) *p*H 7·4 and 1 μmole potassium bicarbonate-^{14}C with 2·5 × 10^5 counts/sec. carbon-14 activity in a total volume of 3·3 ml.

In addition: (1) Adenosine triphosphate 9 μmoles; (2) adenosine monophosphate 9 μmoles.

Experimental conditions: Temperature, 25° C.; exposure period, 1 hr.; reaction terminated by 0·5 ml. 2 *N* sulphuric acid; excess carbon-14 dioxide removed by bubbling with inert carbon dioxide for 15 min.

The addition of reduced diphosphopyridine nucleotide to the medium stimulated the malic dehydrogenase activity, resulting in reduction of labelled oxalacetate to malate. Spectrophotometric determinations had shown the presence of malic dehydrogenase in the preparations. The presence of added malate apparently stimulated carbon dioxide fixation. The addition of malate in the presence of reduced diphosphopyridine nucleotide would result not only in this increase in fixation, but also serve as a trap for the malate formed by the reduction of the labelled oxalacetate. Results from experiments in which the added reduced diphosphopyridine nucleotide was increased twofold in the presence of malate showed a reduction in the total carbon dioxide fixation. The addition of oxalacetate (18 μmoles) to the medium markedly decreased the fixation.

The results show that this particulate preparation from barley roots provides an active system for carbon dioxide fixation through carboxylation of phosphoenolpyruvate. The results shown in Table 2 are representative of the general level of fixation, although in some experiments with added reduced diphosphopyridine nucleotide and malate as much as

Table 2. Carbon-14 Dioxide Fixation in Barley Root Particles. (Activity as percentage of total carbon-14 added)

Treatment	PEP	PEP + DPNH	PEP + DPNH + Malate	PEP + Malate

Decumbin, a New Compound from a Species of *Penicillium*

An organism isolated during a microbiological study of corn spoiled in storage produced an aroma reminiscent of exaltone and crystalline bodies in artificial culture. The chief component of the crystalline bodies has been isolated as colourless, odourless needles, melting at 204° C. We have named this compound decumbin. We have concluded from work to be presented elsewhere that it is a previously unreported dihydroxy, α-β unsaturated lactone ($C_{16}H_{24}O_4$).

The organism producing decumbin has been identified as a strain of *Penicillium decumbens* Thom. (We thank Dr. Kenneth Raper for assistance in specific identification of the mould.) Our strain differed from the American Type Culture Collection No. 10436 (Raper N.R.R.L. 742) strain in that the A.T.C.C. strain did not produce detectable amounts of decumbin in comparable cultures. Both strains produce the characteristic aroma, however, and other characteristics convince us they are the same species.

Among several media tried, the production of visible crystals was best upon a broth prepared by steaming 200 gm. of peeled diced potatoes in 500 ml. of tap water for 30 min. The fluid was drained through one layer of cheese cloth, added to 20 gm. of commercial glucose, and made up to 1 litre. Stationary surface culture was used since the decumbin produced in submerged culture was more difficult to purify. Sterile potato dextrose broth, 300 ml. per rectangular, 2-quart milk bottle, was inoculated with a heavy spore suspension of *P. decumbens*. In about six days at 23–26° C., growth appeared complete with uniform grey-green sporulation and orange droplets of fluid on the surface of the mycelium. Needles of decumbin up to ¼ in. long attached to the submerged side of the mycelium began to appear after about eight days. Cultures were usually harvested after 10–12 days, but a small increase in decumbin yield continued for several more days.

To isolate decumbin, the contents of 100 bottles were strained through two layers of cheese cloth, and the mycelium extracted with three 1-litre portions of boiling methanol. The beer was chilled to 10° C., the precipitate collected, and extracted with 200–300 ml. of hot methanol. The combined methanol extracts were chilled overnight, filtered, diluted with 100 ml. of distilled water, and concentrated *in vacuo* until free of methanol. During the concentration, decumbin crystals began to form and, after chilling to 10° C., were filtered from the aqueous solution and the latter discarded. The average yield of this crude decumbin, m.p. about 190° C., was 278 mgm./l. of medium in a total of 1,404 bottles processed. Individual cultures yielded up to double this amount.

Decumbin was purified by washing the crude crystals with petroleum ether (3 ml./gm.) and recrystallizing them from 50 per cent (v/v) aqueous methanol (33 ml./gm.) and ethyl acetate (60 ml./gm.). The pure decumbin produced by several recrystallizations from these two solvents was not altered by careful sublimation *in vacuo* or drying *in vacuo* over phosphoric anhydride at 100° C.

The solubility of decumbin at 26° C., determined by weight loss from a single crystal after 19 hr. with frequent stirring, was 0·6 mgm./l. of water and 1·2 mgm./l. of 9·5 per cent ethanol. Absolute ethanol dissolved about 24·9 gm./l. These solubility characteristics made biological testing of decumbin difficult. For example, decumbin crystals were tasteless, but a saturated solution in 50 per cent ethanol applied to the back of the tongue was bitter.

Preliminary tests with decumbin showed it to be toxic to rats and to goldfish, and inhibitory to wheat germination, but not an active antibiotic under the tested conditions. Decumbin gave no zones of inhibition when 1 mgm./ml. solutions in 40 per cent (v/v) methanol in water were used in agar cup diffusion tests against *Staphylococcus aureus*, *Escherichia coli*, and *Hormodenrum cladosporoides*. A sample of *Triticum aestivum* var. Knox, of which 92 per cent germinated on filter paper moistened with water, was reduced to 82 per cent germination by 10 per cent (v/v) ethanol in water and to 52 per cent by 1·2 mgm./l. of decumbin in 10 per cent ethanol. Eight goldfish (*Carassius auratus*), average weight 1·7 gm., were each placed in 250 ml. of a filtered aqueous solution of decumbin containing 0·6 mgm./l. In about 4 hr. they became noticeably inco-ordinated. Death followed in about 20 hr.; the smallest (0·9 gm.) succumbed in 12 hr., the largest (2·95 gm.) in 29 hr. Three other fish which had developed definite symptoms (6 hr.) were removed to fresh water; one survived. Control fish in 250 ml. of distilled water remained normal. Young (approximately 100 gm.) albino rats (*Rattus norvegicus*, Wistar–Purdue strain) were fed measured doses of decumbin mixed with about ½ gm. of their normal diet. Fasted rats ate the material readily and consumed the entire dose. From a total of 38 rats dosed with 400 mgm./kgm. body-weight or more, only one rat survived. The toxic symptoms included a rapid onset of loss of appetite (about 2 hr) and diarrhœa (about 6 hr.), followed by increasing lethargy and finally cyanosis, laboured breathing, stupor, and death in about 24 hours. Many rats had slight nasal bleeding. The typical autopsy findings included congestion of the auricles and associated blood vessels with dark blood and fullness of the stomach with undigested food. Ten rats received a dose of 300 mgm./kgm. and two survived. All five rats which received 250 mgm./kgm.

survived. The rats that survived began to eat in about 36 hr. and became apparently normal in five days or less. The acute, oral $LD50$ for rats would be of the order of 275 mgm./kgm. based on these results. Hydrogenated decumbin was not toxic to two rats at 2,700 mgm./kgm. The physiological activity or toxicity of decumbin in mammals, cold-blooded animals and plants is similar to that found with other unsaturated lactones and the loss of toxicity upon hydrogenation is also typical[1].

In addition to its interest as a new compound and one with physiological activity, decumbin was considered as a possible though uncommon grain contaminant. The results of feeding tests with corn meal infected with this mould suggest that decumbin is produced, but not to a degree highly toxic to rats.

Muscle Fibres of the Fast and the Slow Contracting Muscles of the Mesothoracic Leg of the American Cockroach (*Periplaneta americana* L.)

It is well known that some muscle fibres in the coxa of the mesothoracic leg of the American cockroach contract rapidly while others contract slowly[1,2]. Until recently the difference in contraction-speed of insect muscles was attributed mainly to a difference in innervation. Krüger[3], however, discovered that in vertebrates the structures of fast and slow muscles did not differ only in degree of innervation. The specific locomotory muscles apparently consist of fibres that show a uniform distribution of the myofibrils in cross-section (*Fibrillenstruktur*), whereas in posture muscles the fibrils are in small groups, in which the individual muscle fibres are sometimes scarcely discernible. These groups often form angular areas (*Felderstruktur*). The question now arises whether similar differences occur in insect muscles. In order to investigate this problem some muscles of the coxa have been examined in cross-section. They were fixed in 15 per cent formol, Champy, Susa and Bodian 2, and embedded in the usual way in paraffin (alcohol, methyl benzoate, benzol, benzolparaffin). For frozen sections the muscles were embedded in 15 per cent gelatine.

Examination of the whole muscle in cross-section shows that the muscle fibres do not all have the same structure. Two types may be distinguished.

Type A. Muscles 136 and 137 (Carbonell's numbering[4]). In the periphery of the fibres radially arranged partitions are observed, wherein, at greater magnification, the sarcostyles may be discerned. The protoplasm between the sheets is of a lighter colour. In the middle of the fibre is a large central lumen. The nuclei are always situated in the layer of sarcoplasm just under the sarcolemma. This picture is obtained both in paraffin and in frozen sections (Figs. 1 and 2). The radial arrangement is not always equally clear and sometimes not one can be seen in the whole fibre. Fibres without a central lumen are always smaller than the others in cross-section and their fixation is different.

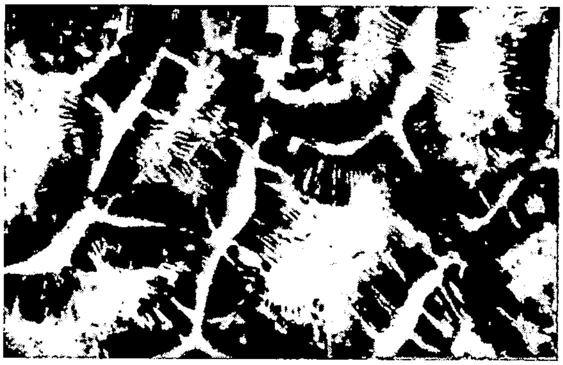

Fig. 1. Cross-section from the fast muscle 137 fixed by Champy paraffin section, iron–hæmatoxylin stain. (× 540)

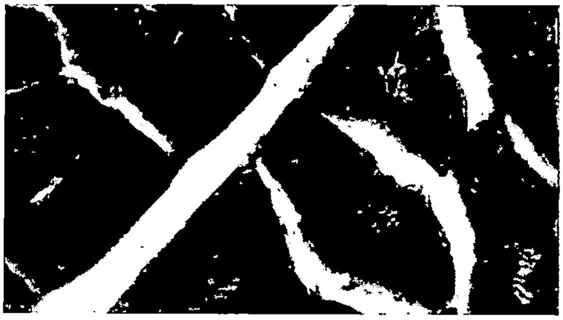

Fig. 2. Right, cross-section from the fast muscle 136. Left, from the slow muscle 135 *e*, fixed by Bodian 2, frozen section, sudan black stain. (× 540)

Type B. Muscles 135 *b*, *d* and *e*. In paraffin sections the fibres of these muscles generally have no central lumen. The sarcostyles are not radially arranged in partitions, but are either arranged in arbitrary rows or scattered all over the fibres. Cross-sections (Fig. 3) show these fibres to be smaller than those of Type *A*. In frozen sections, however, a central lumen is found not infrequently, in which case the sarcostyles are radially arranged (Fig. 2).

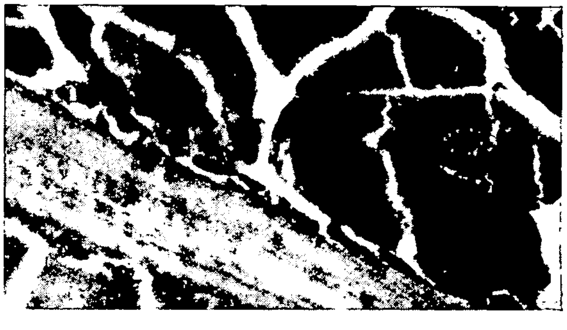

Fig. 3. Cross-section from the slow muscle 135 *d*, fixed by Bodian 2, paraffin section, stained with hæmatoxylin and eosin. (× 540)

With sudan black the fibres of muscles 135 *b*, *d* and *e* stain darker than those of muscles 136 and 137, moreover, with methylene blue the reducing capacity of 135 *b*, *d* and *e* is stronger than that of 136 and 137. As was the case with Type *A*, the nuclei of this type are situated in the layer of protoplasm right under the sarcolemma. Occasionally, however, they may be found nearer the centre of the fibre.

Muscles 135 *a* and *c* do not always give the same picture as 136 and 137; generally these are identical, but in some cases there is a closer resemblance to 135 *b*, *d* and *e*. This phenomenon was observed especially after fixation in Bodian 2.

According to Becht and Dresden[2] the muscles 136, 137 and 135 *a* and *c* are fast-contracting, and 135 *b*, *d* and *e* slow-contracting. The observations described above show that in frozen sections both the slow and the fast muscles are of Type *A*, whereas in paraffin sections the fast muscles are for the greater part of Type *A*, but the slow muscles are always of Type *B*. This difference can be explained only in terms of a different reaction with the fixation liquids, alcohol, methyl benzoate, benzol and paraffin.

This seems to indicate a difference in physicochemical composition that causes the slow muscles to shrink more under the influence of the fixation liquids than the fast ones and that also causes the radial arrangement of the sarcostyles to be lost. Moreover, it is evident that the fibres of the slow muscles contain more lipoids and water and have a stronger reducing capacity than the fibres of the fast muscles.

Masculinizing Action of Pregneninolone on Female Gonads in the Cyprinodont, *Lebistes reticulatus* R.

Several authors have tried to induce sex inversion in *Lebistes reticulatus* experimentally by the use of sex hormones. Berkowitz[1] found that a high percentage of males treated from birth with œstrogenic substances developed ovotestes. The expected result with androgenic hormones would be the production of ovotestes in treated females. Treating young from birth, for a period of two to three months, Eversole[2] and Gallien[3] arrived separately at the same conclusion: that pregneninolone causes the ovaries to undergo a considerable regression, but that they always keep their female structure. Gallien added that after the cessation of treatment the ovaries returned to normal.

Suspecting that their failure to produce masculinization of the gonads was due to the relatively short duration of their experiments, and to the excessively high dose of pregneninolone used, we have carried out the following experiment: 55 animals, all the same brood of *Lebistes*, were treated from birth for a period of 6 months. Treated animals were divided into two groups: the first was given a high dose of 0·03 mgm. of pregneninolone (Ethistérone, UCLAF), three times a week. The second received a low dose of 0·015 mgm. of the same hormone, thrice weekly. A third group of control animals was raised in a manner identical with the treated ones. At the end of the experiment, histological examination of gonads showed that out of 55 treated animals, 37 were males, 15 possessed hermaphrodite gonads and 2 were typical females. Out of 16 control fish, we found 11 males and 5 females.

All treated animals, regardless of sex, showed a transformation of the anal fin into a more or less typical gonopodium. Gonopodia of treated animals were shorter than those of the control ones, and those of the high-dose group were shorter than those of the low-dose group. Specific characters of the gonopodium were present (that is, ventral and dorsal spines, as well as the terminal hook). There were not so many in treated fish as in the controls. Terminal bifurcations, normally found in both sexes, on the fourth, fifth and sixth rays of the anal fin, were partially or completely absent in treated animals. Treatment inhibited growth to a great extent, in both sexes. While treated males had typical body colorations, females had few, if any, body pigments, and when present they were very pale.

The first hæmal spine persisted in all treated animals except one; normally this regresses in both males and females[4,5]. This spine has the same morphology as the following hæmal spines. In almost all treated animals, the gonactines (interhæmal spines) have normal male morphology; in the others the gonactines are completely welded together.

The chronology of development between different secondary sexual characters is disturbed in many cases, due to an acceleration in the development and differentiation of the gonopodium with regard to internal suspensorial elements.

Treated males have testes more or less normal in structure, but in the high-dose group there is an obvious stimulation of spermatogenesis, in such a way that late stages predominate. Sperm ducts are more numerous than in control testes, and their epithelium seems to be highly stimulated.

Gonads of all treated animals, presumed to be genetic females (except two), are transformed into ovotestes. These gonads show different degrees of masculinization. Male elements existing include cysts of spermatogonia, spermatocyte I and II. Cysts of spermatids are less numerous, and spermatophores are rare; whenever present, these are abnormal in structure. In the ovotestes, a certain number of tubules can be distinguished, probably deriving from the epithelium of the ovarian cavity. Those tubules are the homologues of sperm-ducts in female gonads. The cranial region of gonads seems to be more sensitive to the masculinizing action than the posterior region, which sometimes maintains its typical ovarian aspect. In most cases, the persisting ovarian cavity is much expanded. Besides these male elements, and side by side with them, cysts of oogonia, and ovules at different stages of development, can be distinguished. Fully mature ovules are exceptional. Atrophied follicles appear here and there in the gonad.

Preservation of Hæmocyanin

THE hæmocyanins are important proteins since they contain a marker atom (copper) and are remarkably good antigens. Since other investigators may wish to prepare and preserve hæmocyanins, we wish to direct their attention to our observations. In the course of experiments with preparations from *Busycon canaliculatum* and *Limulus polyphemus*, we noted that the dry product obtained by lyophilization (freeze-drying) could not be dissolved in water, in 0·85 per cent saline or in Tyrode's solution (*p*H 3·0–11·0). The hæmocyanin had also lost its oxygen-binding capacity and no longer turned blue when exposed to air. On the other hand, we have kept serum containing hæmocyanin at 4° C. under a layer of toluene, and find that it has retained antigenicity in guinea pigs, rabbits and mice after as long as ten years storage.

Detection of Polythionate in Cultures of *Thiobacilli* by Means of the Folin–Ciocalteu Reagent

A SUBSTANCE giving a typical blue colour with the phospho-tungstate–phospho-molybdate reagent of Folin and Ciocalteu[1] was found to accumulate in cultures of *Thiobacillus thioparus* and *T. thiocyanoxidans* growing in a medium containing thiosulphate. The component in question was not associated with the bacterial cells since it remained in the supernatant fluid of cultures centrifuged at high speeds. The possibility suggested itself that the material involved was an oxidation product of thiosulphate, possibly tetrathionate or one of the other polythionates. These compounds have been reported to be intermediate oxidation products of thiosulphate by the *Thiobacilli*[2].

Polythionate was found to form in cultures of both species when culture fluids were analysed by means of Starkey's qualitative test[3]. This test depends upon the action of potassium hydroxide on the polythionates, converting them to mixtures of thiosulphate and sulphite, products which can be estimated by titration with iodine. Increased titration values during the incubation of cultures would indicate in a general way an increase in the amount of polythionate. The formation of trithionate at the expense of the other polythionates would confound this observation, since this compound on treatment with potassium hydroxide gives a higher iodine titration than do the others. The production of the Folin–Ciocalteu reactive substance was found to parallel the accumulation of polythionate. This was especially noticeable in cultures of *T. thiocyanoxidans*, which failed to produce any reactive substance until late in the incubation period (Table 1).

Sodium tetrathionate was prepared according to the technique described by Partington[4] and was purified by two recrystallizations from ethyl alcohol. The phenol reagent was readily reduced by the purified salt, which was very nearly as active in this capacity as tyrosine. Sulphite also reduced the reagent, but was considerably less active than tetrathionate (Table 2). If formalin were present during the reaction, the colour produced by sulphite was completely eradicated and the density of that produced by polythionate was reduced. The activities of these two substances differ from each other to such an extent as to make untenable the seemingly likely explanation that the mechanism involves the formation of sulphite from tetrathionate. That some alteration does occur was indicated by the necessity for the pre-incubation period in the alkaline copper solution of the usual Folin–Ciocalteu procedure.

Table 1. POLYTHIONATE ACCUMULATION IN CULTURES OF *T. thioparus* AND *T. thiocyanoxidans* AND THE FORMATION OF THE FOLIN–CIOCALTEU-ACTIVE SUBSTANCE

Organism	Incubation (days)	Polythionate*	Optical density of blue colour

Tyrosine, 0·5 μM	0·40	0·39
Tetrathionate, 1·2 μM	0·35	0·19
Sulphite, 30 μM	0·43	0·02
Culture fluid, 1·0 ml.	0·35	0·17

The optical density was measured in the Klett–Summerson photometer, employing the No. 47 filter. The culture fluid was a sample from a culture of *T. thiocyanoxidans* grown for five days in the usual thiosulphate medium, except that it contained a reduced concentration of phosphate. The medium after incubation was centrifuged for 30 min. at 10,000 r.p.m. and the supernatant was used for analysis.

The material formed in the culture fluids was found to behave toward formaldehyde in much the same way as tetrathionate; however, further work is needed to identify the culture material positively as a particular polythionate.

The use of the Folin–Ciocalteu reagent appeared to give an easy procedure for indicating the presence of polythionates in bacterial cultures. Its use for more quantitative purposes will require further study to determine the relative reactivity, if any, of the polythionates other than tetrathionate. Possibly alteration of the reagent and procedure would enhance its specificity.

A Ripple Effect in the Audiogram

In the course of some psycho-acoustic experiments it was found that one observer's thresholds of acuity at two frequencies separated by only a few tens of cycles differed by nearly 10 decibels. Dips in an audiogram are not uncommon; but the difference observed pointed to an uncommonly sharp change of sensitivity. Further tests revealed other equally sharp fluctuations in this observer's audiogram. Eventually a systematic exploration of the right-ear thresholds of this and one other observer was undertaken. Thresholds were measured at 10-cycle intervals over the range 400–3,000 c./s.

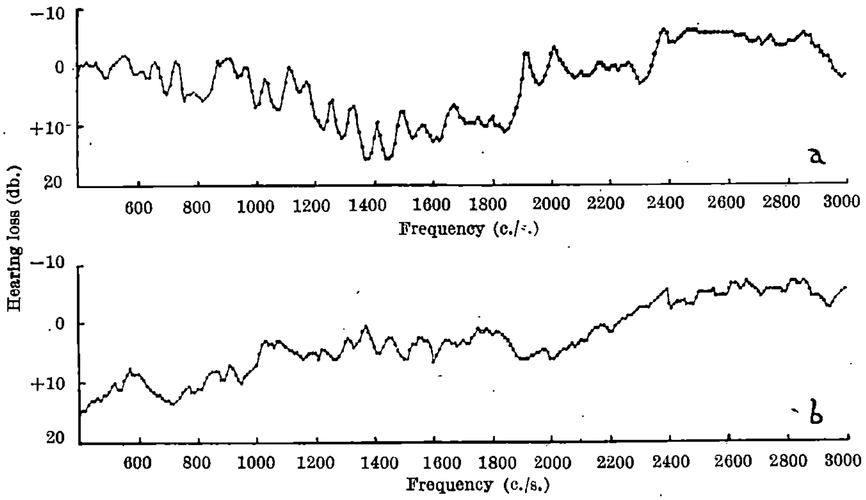

Fig. 1. Audiograms (*a*) for subject *A*, aged 21, and (*b*) for subject *B*, aged 28 years

The remarkable feature of these audiograms (Fig. 1) is the appearance of distinct ripples covering the range of frequencies up to about 2,000 c./s. Further experiments showed (1) that the ripples were stable over a period of at least two months, (2) that the left-ear audiograms also showed ripples, but the periods and amplitudes differed, and (3) that the ripple effect must be a very common, if not a universal phenomenon, since three additional observers also had the same sort of rippling audiograms in the narrower band from 1,000 to 1,400 c./s. This ripple phenomenon seems to have been unnoticed hitherto.

Threshold sensitivity fluctuates quite widely from one test session to another, and even within a single session if it is at all prolonged. To demonstrate the ripple effect it was necessary, therefore, to keep the test sessions short; but each session included measurements of threshold at frequency intervals which were small compared with the period of the ripple, and the frequency band covered was more than twice the period.

Magnitude of Discomfort caused by High Brightness

Hitherto the greatest care has been taken here in the studies of building efficiency to avoid methods of subjective judgment which depend on assessment of sensation magnitude in terms of numbers. For certain reasons, however, a numerical assessment of the magnitude of the sensation of discomfort due to glare was required.

An experiment was designed in which subjects, so far as possible naïve in the context, were asked to adjust conditions in a room with glaring light sources until the sensation of discomfort was 'twice', 'ten times', 'one-half' and 'one-tenth' of the original level of discomfort. Eight out of twelve subjects were able to make judgments without trouble, the other four being either unco-operative or unable to follow what was required of them. The results were consistent and showed less variance than expected. The precise relations, which will be reported elsewhere, are not of importance in the present context because they depend on the experimental conditions.

It is of interest, however, that discomfort magnitude was found not to be correlated linearly with (apparent) brightness of the glaring sources. Whereas, under the given conditions of adaptation, apparent brightness was known from previous work[1] to be related to photometric brightness (luminance) by a power law of the form:

$$M = k\,L^{0\cdot 5}$$

where M is apparent brightness magnitude and L is luminance, the magnitude G assigned to the glare discomfort was found, under essentially the same conditions, to follow a law

$$G = k\,L^{1\cdot 23}$$

In other words, whereas the luminance of the sources must be raised four times $\left(\text{antilog}\ \frac{\log_{10}2}{0\cdot 5}\right)$ to appear twice as bright, the sources will appear twice as uncomfortable (for glare) if their luminance is raised only 1·8 times $\left(\text{antilog}\ \frac{\log_{10}2}{1\cdot 23}\right)$.

If these data are valid, it raises an important principle in practical engineering matters involving subjective judgments of magnitude, especially if this principle is applicable in other modalities, such as noise. This is, that if a stimulus gives rise to both a primary sensation (loudness or brightness) and also an associated secondary sensation (pain or discomfort), it does not follow that the magnitude of the secondary sensation is directly or simply linked to the magnitude of the primary sensation. Hence, if we wish to find out about discomfort or pain, we must assess discomfort or pain directly in relation to stimulus energy, and must not make implications from brightness or loudness magnitude assessments.

The experimental work was undertaken by Mr. R. C. Bradley (Cornell University) working at the Building Research Station with a grant from the Illuminating Engineering Research Institute of the United States.

Interaction between Consecutive Responses in a Hemileucid Moth, and the Evolution of Insect Communication

Moths of the neotropical Saturnioid family Hemileucidae perform a special movement on assuming the resting position from any preceding activity, which has been termed 'rocking'[1]. It is rigidly co-ordinated, and consists of fast, rhythmic side-to-side oscillations of the entire animal. This movement is unique to the Hemileucidae, and appears to be a highly conservative character within that family, for it occurs in all species so far examined, irrespective of either size or mode of protective coloration[2]. Its function, if any, is unknown, but it is not concerned with the sexual responses of either sex, nor do the moths possess any known non-sexual social behaviour. The strength of this response may be scored as the number of complete oscillations performed; an analysis has shown that the strength of rocking executed by unconstrained moths of the Brazilian species *Automeris aurantiaca* Weym. is related to the nature of the sequence of acts preceding it[1].

The experiment here reported investigates the effect of different periods of forced, tethered flight upon the strength of the rocking response, at two different intervals after eclosion. Pupal development and emergence were allowed to proceed at about 25° C. Moths stored for intervals after eclosion were transferred to 20° C. in continuous artificial light and remained undisturbed throughout that period. They were suspended for flight in one of two ways. Either a small tab of paper was attached to the dorsal surface of the thorax with a quick-drying cellulose adhesive, and held in a clip, or a small dorso-lateral pinch of the second abdominal tergite was held in fine curved artery forceps, from which it could be released as required. The method of suspension did not influence the results. All moths were de-alated at the time of preparation. They were stimulated to fly at 26–29° C. by the tarsal reflex[3], at 4–8 hr. (26 moths) and 24–48 hr. (15 moths) after eclosion, immediately placed on a standardized vertical surface, and the number of rocks performed counted (Fig. 1). The strength of the rocking response increases with increase in preceding duration of flight, to which it bears a simple linear relationship which shifts as the moths age. For moths 4–8 hr. old, $y_1 = 2{\cdot}45 + 0{\cdot}790x$; and for moths 24–48 hr. old, $y_2 = -0{\cdot}75 + 0{\cdot}663x$. The difference between the two regression coefficients is not significant ($P < 0{\cdot}2, > 0{\cdot}1$).

Moths may be re-tested for the strength of the rocking response at intervals after settling following flight; in moths of both ages it is stable, certainly for periods of 30 min., and probably for at least 90 min., and would seem not to be affected by intercalated activities unrelated to flight. Further preliminary experiments, to be reported in full elsewhere, suggest that these relationships are not mediated either by feed-back from peripheral receptors[4] or by the chemoreception of the state of metabolic reserves[5].

Results of this kind have been obtained in studies of the behaviour of other arthropods[6]. They suggest that the arthropod nervous system may be so constructed as necessarily to store information about its past performance. The present case is of particular interest, for it concerns a rhythmic response. Recent work[7] tends to confirm the prediction[8] that the rhythmic 'waggle' phase of the honey-bee dance is a potentially important carrier of information about distance from hive to food-source when this is greater than 50–100 metres. The relationship between distance flown and the number of oscillations in each repetition of the straight run of the dance is simple and nearly linear over much of its range[7]; it differs from certain other quantitative features of the dance[9] in that it is not affected by the sugar-concentration of the food-source.

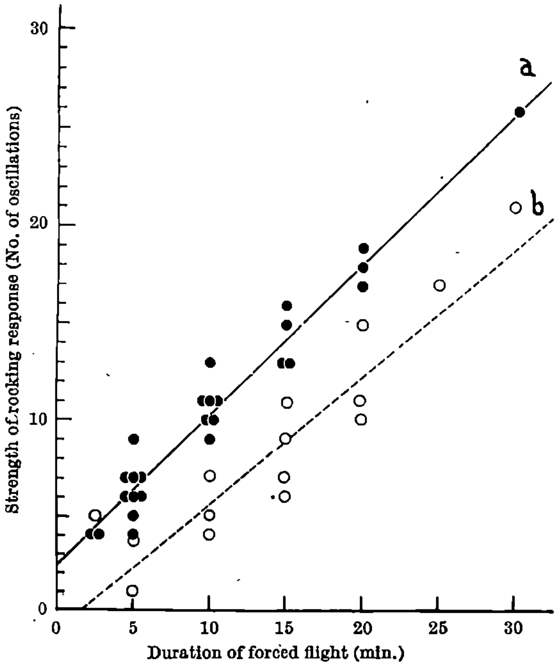

Fig. 1. The relation between the duration of forced flight (abscissa) and the strength of the rocking response (ordinate), for *Automeris aurantiaca* of two different ages: (*a*) 4–8 hr.; (*b*) 24–48 hr.

Dethier[5] has shown that those features of the bee-dance which show simultaneous dependence upon flight-distance and sugar-concentration may plausibly be interpreted in terms of the known mechanisms governing the central regulation of taste-thresholds, once it is assumed that feeding is itself the stimulus to dance. But such a mechanism cannot be assumed to mediate the 'waggle' phase of the dance in its quantal aspect, and for this some alternative evolutionary precursor must be found. Such a system would appear to be involved in the interaction between flight and settling behaviour in *Automeris*, which already possesses two of the most salient features of the 'waggle' dance, namely, the linear relationship described above, and a considerable measure of quantitative temporal stability. It is not, however, used in communication. It is likely that a full understanding of the causal basis of the bee-dance will only be possible when mechanisms of both kinds are taken into account.

The present results do not permit any very exact comparison of the two performances. However, if it is assumed that foraging bees fly at an average speed[4] of 14 m.p.h. ($\equiv 375{\cdot}5$ m./min.) and that both the outward and return journeys are registered in the waggle phase[7], then for the bee, 3·34 oscillations $\equiv$ 1 min. of flight, as compared with 0·79 oscillations for moths 4–8 hr. old. *Reproducible* information, therefore, is stored with less efficiency in the moths than in the honey-bee. These results emphasize a further problem: the presence of a teleologically perfect relationship of this kind in a non-communicating insect implies that it is dangerous to assume that the mere presence of an isolable factor in the bee-dance necessarily means that it is used in communication.

These experiments were started during a visit to the Ornithological Field Station, Madingley, Cambridge, part of the expenses of which were met by a Parliamentary grant-in-aid administered by the Royal Society. I am also indebted to Prof. V. G. Dethier, Johns Hopkins University, for a discussion of some unpublished work on *Phormia*.

Feulgen-Positive Cytoplasm of *Molgula* Eggs

The Feulgen technique has been used with success for chromosome studies in whole mounts of the eggs of marine animals such as *Arbacia* and *Chaetopterus*[1]. Hundreds of specimens can be fixed, stained and mounted in an hour or two—a fraction of the time and effort involved in an embedding-sectioning procedure.

Recently, in expectation of preparations suitable for scoring chromosomal aberrations (investigations supported by a U.S. Atomic Energy Commission grant to the Marine Biological Laboratory), I applied exactly the same methods to fertilized eggs from the ascidian *Molgula manhattensis*. To my surprise, the cytoplasm stained so deeply that nuclei and chromosomes were completely obscured. Several papers of historical interest[2] report intense cytoplasmic coloration of *Molgula* eggs with non-specific staining methods. However, deep staining with the classic means of demonstrating deoxyribonucleic acid was not expected.

A maturing series of oocytes carried simultaneously through the solutions demonstrated that the stainable material accumulated during maturation. Only mature oocytes stained deeply.

Substituting one fixative for another made little difference. The cytoplasm was Feulgen-positive if Gilson's fixative, which contains no aldehyde, was used instead of Kahle's fluid. Digestion with cold perchloric acid (10 per cent for 11 hr. at 4° C.) did not eliminate the cytoplasmic stainability. This is a recognized method of removing ribonucleic acid. The Schiff reagent was a standard batch which was performing normally in the staining of *Habrobracon* (wasp) eggs.

Brachet[3] has referred to positive Feulgen reactions of the ooplasm of higher chordates but was unwilling to admit that deoxyribonucleic acid could be responsible. Amphibian and hen eggs were outstanding examples. Since that time, scattered reports of cytoplasmic deoxyribonucleic acid or deoxyribosides have appeared for a variety of organisms[4], and a hypothesis has emerged that the cytoplasm serves as a deposit for nuclear building materials required promptly and in quantity during cleavage[5].

The cytoplasm of *Molgula* eggs suggests itself as material worthy of attention by biochemists interested in morphogenesis.

Relation between Breeding and Ecdysis in Cirripedes

In all major groups of Crustacea except in cirripedes it is well known that breeding is closely bound up with the moulting cycle. First, the male generally copulates with a female which has just moulted. Secondly, the moulting cycle is often interrupted while the eggs are being carried so that eggs are not lost by the shedding of the cuticle to which they are attached.

The Cirripedia are exceptional in being hermaphrodite and in having the egg masses lying free in the mantle cavity during incubation. As a result they do not necessarily lose them when they moult[1]. Crisp[2] suggested that a moult might be expected to accompany copulation as it does in other arthropods. Barnes and Barnes[3] later discussed the same idea, and without giving any definite evidence suggested that it occurred after fertilization.

During the past three years we have investigated six species of sessile barnacles, *Balanus balanoides* (L.), *Balanus balanus* (L.) (= *B. porcatus* da Costa), *Balanus crenatus* Brugière, *Balanus perforatus* Brugière, *Elminius modestus* Darwin and *Chthamalus stellatus* Poli.

In none of these species have we found evidence for a moult soon after copulation. On the contrary, the intermoult period is prolonged when the barnacle is carrying embryos, although the extension of the intermoult period is not absolutely regular. Normally ecdysis does not occur until after the young have hatched and escaped from the mantle cavity.

When hatching is delayed by withholding food[1] the intermoult period is further prolonged so that in the majority of individuals moulting still occurs just after liberation. Sometimes the moulting cycle seems to reassert itself before liberation; but the eggs still develop normally and a further moult usually occurs after liberation. Very occasionally developing eggs are ejected from the mantle cavity; but this usually occurs under abnormal temperature conditions and is not necessarily related to moulting.

In *B. balanoides* the breeding cycle is long and the period of anecdysis, which commences with the copulation in November, lasts until sometime between December and March, varying with the individual (Fig. 1). In this species the first cast skin after the period of anecdysis, irrespective of whether fertilization has occurred or not, contains all the tissues of the penis. The penis is thus separated by an abscission layer of new cuticle, and a new penis gradually

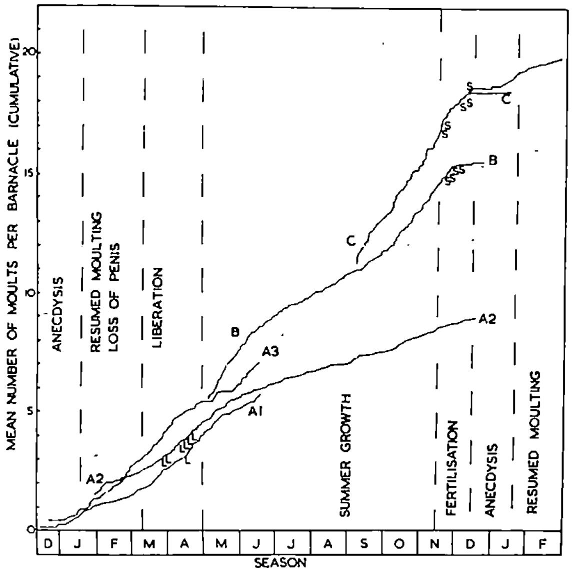

Fig. 1. Moulting-rate of small groups of *B. balanoides* kept without food. A_1, A_2, A_3, groups of fertilized barnacles showing resumption of casting after anecdysis; A_1, 5–7° C. temp.; A_2, sea temp. (8° C. rising to 15° C.; A_3, 13–15° C.; *L*, liberation of nauplii. *B*, groups of barnacles which had previously fed in the sea during spring. *C*, groups of barnacles fed in the sea until September, showing anecdysis; *S*, sperm pool indicating fertilizations

develops before the onset of the next breeding season. This remarkable phenomenon is natural, and is not the result of abnormal laboratory conditions. It occurs in the sea, since barnacles from the shore in January have either a complete penis or none at all. Moreover, it has been shown to occur regularly each year since 1954 in the laboratory and is therefore a part of an annual rhythm.

We have also found that individuals of this species which have moulted less than about a week previously are better able to act as females, fertilization occurring more frequently than in barnacles which had cast the skin more than a week before. In none of the other species could this effect be demonstrated, perhaps because the normal intermoult period of only 6–10 days is so short that every individual can be regarded as having recently moulted.

In *B. crenatus*, *B. perforatus*, *Elminius modestus* and *Chthamalus stellatus* embryonic development is relatively short, especially at higher temperatures, and after the brief interval for incubation normal moulting is resumed, its rate depending on the food supply and temperature. In *B. balanoides*, on the other hand, the moulting-rate only gradually increases after anecdysis, its resumption depending upon the amount of food taken in and the temperature. The inter-moult period usually reaches the normal summer value of 10–15 days by May. If the individuals are not fed in the spring, hatching is delayed and the resumed moulting continues at a slower rate (Fig. 1, curve A_2). The slower rate of moulting after anecdysis is not, however, a direct consequence of carrying the eggs but is due to prevailing lower temperature in April and lack of food. The moulting-rate does not increase appreciably when the eggs are artificially hatched with an extract of shell tissue[1]; but it does increase if the barnacle is fed or the temperature raised.

The continued regular casting of starved specimens which are losing rather than gaining weight is interesting. It suggests that ecdysis may have another function in addition to that of allowing for growth. Indeed, where casting is disadvantageous, as it is for the caterpillars of some butterflies which live with ants (for example, *Maculinea arion*), the body can grow four or five times in length by simply stretching the skin[4]. Perhaps another important function of ecdysis in filter-feeding Crustacea is to renew the fine setæ and so prevent the filtering apparatus from becoming clogged and inefficient.

These observations, which bring the Cirripedia in line with other arthropods, will be published in detail elsewhere.

Plant Growth on 'Fly Ash'

In a previous communication[1], reference was made to research work in progress at Leeds on the reclamation of land covered with pulverized fuel waste ('fly ash'). Further to that work, we have concluded that aluminium and manganese, as found by Rees and Sidrak[2], are not the dominant causes of the toxicity in the 'fly ashes' investigated at Leeds.

Evidence from records on the tolerances of crop plants to 'fly ash', together with observations of leaf symptoms, suggest that boron is the dominant toxic element, and this theory has been strengthened by direct agronomic tests, together with relevant chemical analyses. The evidence is summarized below.

Information gained from pot and plot experiments has enabled a preliminary classification of agricultural and horticultural crops into the following three main groups on the basis of their ash tolerance:

Tolerant: Fodder beet, mangels, red beet, spinach, swede, turnip and sweet clover.

Moderately tolerant: Clovers, lucerne, kales, rape and mustard, other cultivated members of the Cruciferae and ryegrass.

Sensitive: Cereals (especially barley), peas, vetches, beans, potatoes, lettuce, carrots, parsnips, buckwheat and cocksfoot.

This list bears close resemblance to those of Eaton[3] and Berger[4], who grouped crops according to their boron tolerance.

Visual symptoms which develop on plant leaves under conditions of boron toxicity have been described by Eaton[3]. There is a close similarity between the recorded symptoms and those which have been observed on plants grown in 'fly ash', although the leaves of beets and kales in our experiments have not shown the characteristic marginal scorch. Barley

* Mild leaf symptoms took the form of leaf tip die-back, severe symptoms showed in addition a white interveinal striping of the lamina.

leaves, however, have consistently developed the marginal scorch, leaf tip die-back and brown necrotic spots and blotches associated with boron toxicity. Christensen[5], investigating the cause of non-parasitic spotting of barley leaves, was able to reproduce the spotting experimentally by adding borax or boric acid to a soil which otherwise produced healthy plants. The lesions which occur on barley leaves under conditions of manganese deficiency and toxicity[6] do not appear to be typical of those caused by 'fly ash'.

A small, non-replicated pot experiment was designed to compare the growth of barley on 'fly ash'/soil mixtures and on soil irrigated with solutions of borax. Three 'fly ashes', *A*, *B* and *C*, were used in this experiment. The leaf symptoms which developed on plants grown in 'fly ash'/soil mixtures were identical to those developed on the boron-irrigated plants. The 'soil' results are presented in Table 1 and the 'ash' results in Table 2.

Further evidence of boron toxicity has resulted from chemical analyses of oats from a replicated pot experiment specifically designed to compare the toxicities of untreated and acid-treated 'fly ash' when incorporated in increasing quantities with an inert medium of sand and vermiculite. The dry weights of oats, their boron contents and leaf symptoms are summarized in Table 3.

The accumulated evidence suggests that boron is a major component of the 'toxic principle' in 'fly ash' and determinations of the water-soluble boron contents confirm that this element is present in high concentration, samples *A*, *B* and *C* containing 19, 18 and 51 p.p.m. respectively. The degree to which the toxicity manifests itself will be dependent partly on the source of the ash and the degree of weathering or leaching to which it has been subjected. It must be emphasized that work referred to in this communication has been carried out on unweathered ash, that is, that taken directly from the pulverized fuel furnaces. (Boron has been determined after Higgons[7].)

This work has been made possible by a research grant to the University of Leeds by the Central Electricity Authority to which full acknowledgment is made.

Effect of a Single Light Exposure on Germinating Broad Bean Seeds

In the course of investigations into the cytological and anatomical aspects of etiolation in *Vicia faba* L. (broad bean), experiments were carried out to determine the stage at which the germinating seeds first become sensitive to light in regard to subsequent development of the internodes.

Seeds were soaked for 24 hr., planted in soil and grown for 12 days. Throughout the period of soaking, during planting and for the whole period of growth the material was kept at 20° C. and in complete darkness, except for a single exposure to light for 2 hr. at approximately 600 ft.-candles. The seeds were divided into batches of fifty, each batch being given a single exposure to light, starting at various intervals up to 7 days from the beginning of soaking. As a control, one batch was given no light. The internode length of all seedlings was measured at the end of the 12-day growth period. Fig. 1 summarizes the results.

At 12–14 hr. after the beginning of soaking, when the testa is still intact, a 2-hr. exposure to light gives rise to a reduction of approximately 15 per cent in the mean ultimate length of the first internode as compared with seeds soaked and grown in complete

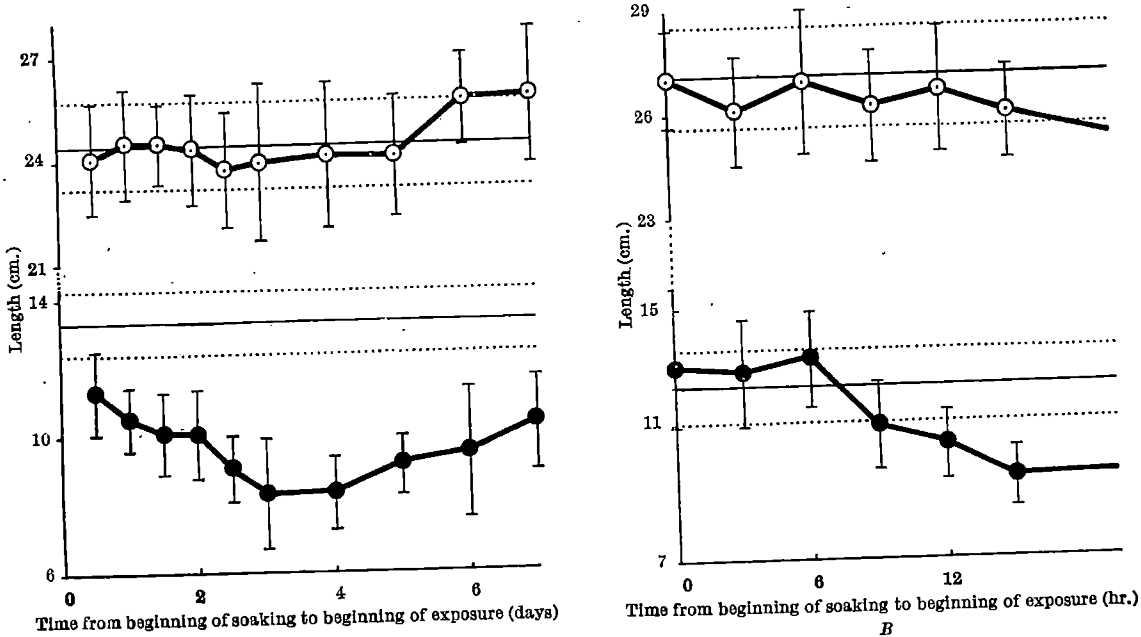

Fig. 1. Effect of a single light exposure on germinating seeds. ⊙—⊙—⊙, Whole shoot; ●—●—●, first internode. The vertical bars indicate the fiducial limits at the $P = 0{\cdot}05$ level. The horizontal lines represent the dark control values and their fiducial limits

darkness. The reduction reaches a maximum of approximately 35 per cent when the light is given at 3–4 days.

From the results it appears likely that the sensitivity to light may develop earlier than 12 hr. This view is supported by the observation of a pronounced increase in the frequency of plants in which a third internode elongates after an exposure to light as early as 6–8 hr. This development of the third internode, coupled with a general increase in the length of the second internode after early light treatment, appears to compensate for the reduction in length of the first internode, so that the effect of light is not revealed in the ultimate total length of the shoot.

The situation seems to be similar to that shown in *Avena* by Lange[1], Avery *et al.*[2] and Goodwin[3]. Thomson[4], also working on *Avena*, concludes that light accelerates whatever growth processes are going on while the light stimulus acts, exposure early in the course of either cell division or cell elongation accelerating that phase of growth. Exposure when either phase is well under way hastens transition to the next phase and reduces the final number or length of cells. The first internode in *Avena* is thus suppressed by light given at one day or earlier when cell division is already in progress.

In *Vicia*, however, the light sensitivity, as revealed by suppression of the first internode, appears to develop in the partially soaked, intact seed immediately the embryo has taken up water, although no cell division was observed until the third day. It may well be that sensitivity has already developed in the maturing seed and is one of the factors contributing to the great variation in development within batches of seeds germinated and grown in the same conditions. This possibility is being investigated.

Apart from these considerations, the practical implications of our findings for etiolation and light-growth studies is that seeds must be soaked in complete darkness if a true picture of the completely etiolated plant and the effects of light during subsequent growth is to be obtained.

Effect of Gibberellic Acid and Kinetin on Growth of the Primary Leaf of Dwarf Bean (*Phaseolus vulgaris*)

IN the course of experiments on the effect of gibberellic acid on leaf area it was found that this substance accelerated expansion of the primary leaf of dwarf bean (var. Canadian Wonder); but the final area attained was identical with that of leaves receiving no treatment. Kinetin (6-furfurylaminopurine), on the other hand, depressed the rate of leaf expansion. Areas were estimated by use of a regression equation relating to the product of length × breadth calculated from measurements of more than 100 leaves. This equation is: area (cm.^{2}) = $0{\cdot}8682\ (\pm\ 0{\cdot}0196) \times p + 3{\cdot}19$, where p is length × breadth in cm.^{2}. The application of the allometry formula indicated that treatment produced no change in shape of leaf, so it is justifiable to apply this regression equation irrespective of treatment. The leaves were sprayed as soon as they had unfolded and assumed a horizontal position (length about 5·0 cm.), and were kept in darkness for about 16 hr. in case kinetin was destroyed by light. The average daily increments in area plotted for the mean period are shown in Fig. 1.

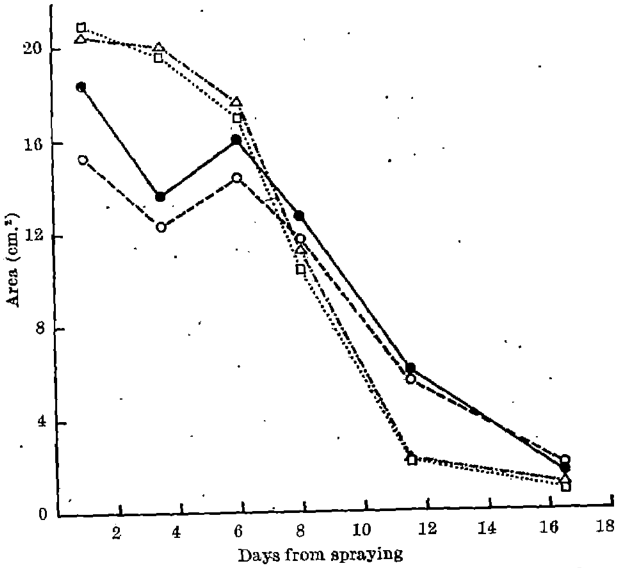

Fig. 1. Mean increase in area per leaf per day. ●—●, Control; ○—○, kinetin; □···□, gibberellic acid; △—·—△, gibberellic acid + kinetin

Leaves sprayed with gibberellic acid (50 p.p.m.) or gibberellic acid + kinetin (0·1 p.p.m.) at first increased in area at a greater rate than the control. Kinetin alone slightly depressed the rate of leaf expansion. About six days after spraying, the position was reversed and the control and kinetin-sprayed plants increased in area at a greater rate. The final area of the leaves sprayed with gibberellic acid was the same as that of the controls, but kinetin alone depressed final area (Table 1).

Table 1. Mean Final Area of Primary Leaf of Dwarf Bean

Treatment	Final area (cm.^{2}) *a*	 *b*
(–)	61·4	205·6
Kinetin	54·8	187·5
Gibberellic acid	62·4	199·4
Kinetin + gibberellic acid	61·2	202·4

a, Growing point intact; *b*, growing point removed.

It is to be noted that the depressing effect of kinetin was overcome in the presence of gibberellic acid. It was thought possible that the growth of the primary leaves might be affected by initiation of growth of the main axis (which was greatly extended by gibberellic acid) and that the subsequent depressing effect of gibberellic acid might be due to this. Precisely similar results were obtained, however, when the growing point was removed before treatment, except that the primary leaves in all treatments reached a greater final size (Table 1).

Morgan and Mees[1] found that gibberellic acid at first stimulated growth of grass swards but afterwards the yield was depressed and the dry matter and crude protein yields at the second cut were depressed by approximately the amount of increase at the first cut. Leben and Barton[2] also found an ultimate depressing effect of gibberellic acid on growth of grass. Humphries[3] found that gibberellic acid at first increased and then diminished leaf area and dry-matter production in the potato plant. In addition, it was found that gibberellic acid overcame a depressing effect due to kinetin.

Thus, the effect of gibberellic acid on the primary leaf of dwarf bean is analogous to its effect on whole plants in the instances quoted, namely, a preliminary stimulation and subsequent depression of growth.

Inhibitory Effect of Gibberellins on Nodulization in Dwarf Beans, *Phaseolus vulgaris*

Gibberellins of fungal and higher plant origin are now widely used in experimental plant physiology, and are known to produce a great variety of effects on the growth and development of many different plants[1]. With very few exceptions, the effects noted are promotive, even high concentrations of gibberellins being relatively non-toxic, to both plants and animals[2]. The results to be reported in this communication, demonstrating an inhibition of nodule formation in dwarf beans, are therefore of interest.

Commercial dwarf beans (*Phaseolus vulgaris*) were planted in 3-in. clay pots containing potting soil supplemented with limestone. The plants were grown in a greenhouse uncontrolled as to temperature and light conditions. On the sixth day after planting, the pots were divided into 5 equal groups of 4 plants each, and on the seventh day each plant was watered with 20 ml. of a 1 : 500 (w/v) 15 : 15 : 15 fertilizer to ensure an adequate level of mineral nutrition during the growth experiment.

Eleven days after planting, when the mean height of the plants approximated 15 cm., the groups were sprayed, according to different schedules, with 'Gibrel', a Merck product containing 0·005 per cent potassium gibberellate in an aerosol preparation. Thirteen days later, the plants were carefully removed from the soil and various measurements made. The results are presented in Table 1. Among the notable effects of the gibberellin treatments are: (*a*) up to fourfold enhancement of elongation without significant effects on fresh weight; (*b*) enhanced lateral bud growth; (*c*) decreased dry weight in plants given daily sprays; (*d*) greatly decreased nodulization, especially in those plants subjected to daily sprays.

Table 1. Effects of Repeated Applications of Potassium Gibberellate on *Phaseolus vulgaris*. All Plants were examined on the Thirteenth Day of Growth after Spray Application

Group	Spraying schedule	Average height to terminal bud (cm.)	Average lateral bud growth (cm.)	Average fresh weight (gm.)	Average dry weight (gm.)	Degree of nodulation
A	Controls (no spray)	27·5	27·5	8·8	2·0	Numerous large clusters
B	Every 5th day	112·75	148·75	11·2	2·1	6–8 small nodules per plant
C	Every 4th day	93·25	93·25	8·1	2·1	9 small nodules on one plant
D	Every 3rd day	100·0	145·0	8·2	2·2	5–6 small nodules per plant
E	Every 2nd day	91·5	150·5	8·8	2·3	2 small nodules on one plant
F	Daily	93·5	159·5	9·4	1·5	None

Table 2. Effect of Gibberellin Applications to Soil Alone and to Plant and Soil. Measurements were made 19 days after planting, the plants having been sprayed only once, 5 days after planting

	Treatment		
	None	Soil only	Soil + plant
No. of plants	16	14	17
Terminal bud height (cm.)	24·2	36·6	75·0
Average dry weight per plant (gm.)	0·82	0·95	0·50
Percentage of plants showing nodulization	62·5	76·5	14·2

In a subsequent experiment, it was shown that gibberellin treatment of the soil was ineffective in inhibiting nodulization, though some growth effects were readily apparent. Gibberellin sprays applied to the plant and soil were more effective, both in increasing elongation and in decreasing nodulization (Table 2).

Although the mechanism of the inhibition of nodulization is not clear from these experiments, the results indicate the need for caution in the application of gibberellins to leguminous plants. They also suggest the possibility that nodulization may result from a local accumulation of gibberellins.

These experiments were performed as a project supplementing classroom exercises in plant physiology at a National Science Foundation-sponsored Summer Institute for Teachers held in the summer of 1957 at Iowa State Teachers' College at Cedar Falls, Iowa.

Mitotic Delay in Irradiated Roots of *Vicia faba* : the Effect of Oxygen

It is well known that the presence of oxygen during the irradiation of biological materials by X- or gamma-rays usually increases the amount of radiation damage. At the cellular level a considerable amount of quantitative data exists on the effect of oxygen, given during irradiation, on the yield of chromosome aberrations[1], but little information is available concerning the influence of oxygen on the amount of mitotic inhibition. Early work on the fall in mitotic index values of broad bean root tips[2] and the more recent studies on mitotic rates of *Chortophaga* neuroblasts[3] and *Tradescantia* microspores[4] have all indicated that the degree of mitotic inhibition is dependent on the amount of oxygen present during irradiation.

We have investigated the oxygen effect on mitotic delay in broad bean root tips with the view of making a comparison with parallel results which we are obtaining for chromosome breakage and root elongation in this material. In our experiments gamma-rays from a cobalt-60 source were used, and the primary roots of seedlings were irradiated while maintained at 19° C. in aerated or oxygen-free water (nitrogen water, obtained by bubbling nitrogen). For irradiation the seedlings were transferred from their normal aerated water into the aerated or nitrogen water of the irradiation chamber for 5 min. before irradiation. Doses of 109 r. and 192 r. were used and both doses were given in 4·9 min. It was shown that a 10-min. immersion of control seedlings in nitrogen water did not affect mitotic rate.

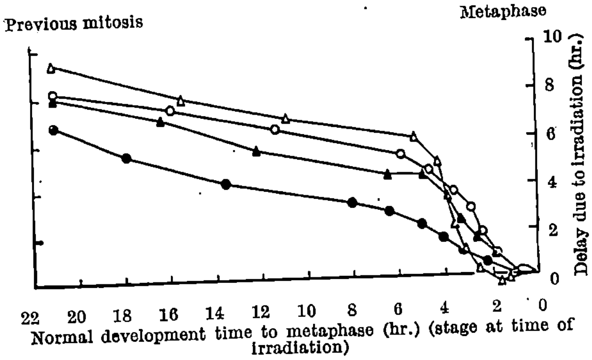

Fig. 1. Delay in reaching metaphase of cells irradiated at various stages of interphase. Normal mitotic cycle time, 21 hr. △, 192 r. in aerated water ; ○, 109 r. in aerated water ; ▲, 192 r. in nitrogen water ; ●, 109 r. in nitrogen water

Mitotic delay was measured by our colchicine method[5] which involved comparing the rate of accumulation of cells at metaphase in control material with the rates in the irradiated materials, at closely spaced time-intervals after irradiation. From these results we obtain the time required for cells to reach metaphase after being irradiated at any given point in interphase. The excess time over cells of control material, that is, the mitotic delay, is illustrated in Fig. 1.

The results show a marked oxygen effect for mitotic delay, and this effect is apparent for cells irradiated at any stage of interphase, the shape of the air and nitrogen curves being very similar. It is clear from these results that a dose of 192 r. in nitrogen is less effective in delaying the progress of cells through the mitotic cycle than a dose of 109 r. in air. Comparisons of the delays induced by both doses of radiation, in air and nitrogen, for cells which were more than 6 hr. from metaphase at the time of irradiation, gives an air/nitrogen ratio of about 2. This compares with the air/nitrogen factor of 2·4 for inhibition of root growth[6] and the factor of 2·2–2·5 which we have found for the production of micronuclei.

Further details of these experiments will be published elsewhere.

Natural Cross-Pollination in Lettuce, *Lactuca sativa* L.

SELF-FERTILIZATION in *Lactuca sativa* L. is commonly regarded as being complete, although the inflorescences are visited by insects and the possibility of cross-pollination does occur[1,2]. Some indication that natural crossing takes place was provided by the fact that progenies raised from seed, taken from random plants grown in adjacent plots of a trial of a large number of varieties at Wellesbourne, have contained widely different proportions of off-types. An experiment was carried out in 1955, therefore, to ascertain the amount of crossing which might occur.

Two varieties were planted in each of four plots, these consisting of 15 rows of 11 plants, the odd rows and alternate plants in the even rows being of a pigmented variety, while the remaining plants were of an unpigmented variety. Each unpigmented plant was thus surrounded by 8 pigmented ones. The gene for anthocyanin pigmentation[3] behaves as a dominant in F_1.

The first plot contained two winter lettuce varieties which flower rapidly in long days[3], while the second plot, which was sown at the same time as the former, contained two varieties of summer lettuce. The remaining two plots consisted of the same varieties of summer lettuce as the previous one, but were sown at three-weekly intervals. The flowering periods of all plots differed from one another, and times of flowering within plots were made to coincide by the removal of any capitula from unpigmented plants which opened before those of the pigmented ones. Seed collected from the unpigmented plants was sown in 1956 and the number of pigmented and of non-pigmented seedlings was recorded.

The weather in 1955 was dry and warm, encouraging insect activity; but the lettuce did not appear to have the same abundance of pollinating insects as brassica plants flowering in the vicinity. Insects most attracted by the open lettuce capitula were various species of hover-fly and a few butterflies. Bumble- and honey-bees were rarely seen on the plants. This comparative scarcity of insects suggested that the proportion of hybrids produced would be low, and this was confirmed by the results from the earlier flowering plants. The percentage of hybrids produced by the later flowering plants, however, showed a sharp increase as indicated in Table 1. It has been suggested by Mr. J. A. Dunn, of this station, that this increase was probably due to the seasonal rise in the hover-fly population, and it appeared probable that hover-flies were the main pollinators in this experiment with lettuce.

Unsuccessful attempts were made to use hover-flies as pollinators by enclosing them in muslin bags together with flowering lettuce plants; in every instance they made continual attempts to escape, and lived a maximum of only 36 hr.

Table 1

Plot No.	Varieties (pigmented variety first)	Flowering period	Mean per cent cross-pollination
1	Rouge à pomme dure d'hiver, Lees Immense	July 18–Aug. 26	0·75±0·053
2	Mignonette, Cheshire Green	Aug. 6–Sept. 8	0·15±0·009
3	Mignonette, Cheshire Green	Aug. 13–Sept. 16	3·19±0·186
4	Mignonette, Cheshire Green	Aug. 30–Sept. 26	11·52±2·749

The statistical analysis of the results showed that plants flowering late in the season exhibited a significant increase in the percentage of natural cross-pollination. With the exception of three plants in plot 3, cross-pollination during each of the different flowering periods was entirely at random.

Sex Chromosomes in the Hop *Humulus lupulus*

STUDIES of meiosis in male plants of the hop *Humulus lupulus* have resulted in conflicting reports on the nature of the sex chromosomes. Winge[1] and Jacobsen[2] have described an unequal pair of sex chromosomes which Jacobsen also identified in the somatic cells of male and female plants. Sinoto[3] found no heteromorphic pair, but described a chain of four sex chromosomes which he designated $X_1Y_1X_2Y_2$. No evidence was put forward in support of this interpretation. Ono[4], however, demonstrated in *H. lupulus* var. *cordifolius* (the wild hop of Japan) that a quadrivalent occurred in meiotic divisions in the male, but not in the female plant. More recently[5] he has described the occurrence, in a number of male varieties, of five different sex chromosome types, one of which is a homomorphic pair, two are heteromorphic pairs with different length ratios, and two are complexes of four chromosomes, also with differing length ratios.

During the 1957 season meiosis was studied, at Wye, in six male plants, five of which were seedlings from open pollination of wild Canadian or New Mexican female plants and one (No. 15) was of unknown origin. In all six a heteromorphic pair of chromosomes could be distinguished. In four of these males a quadrivalent association was found in addition to the unequal pair. Whereas the latter was a constant feature of all divisions, the quadrivalent was not present in a number of nuclei (Fig. 1,

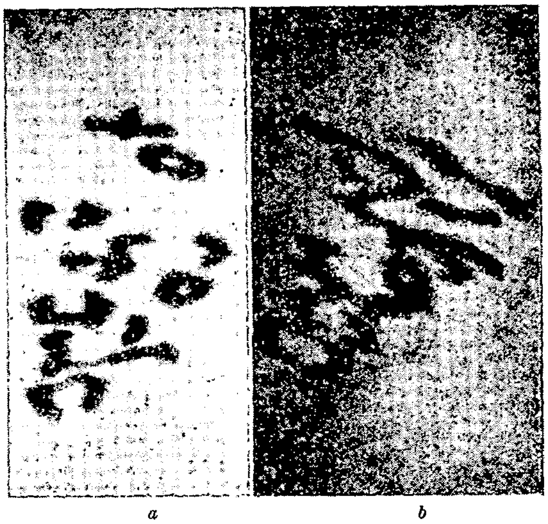

Fig. 1. Meiosis in male 321. *a*, Nucleus containing a heteromorphic pair and nine bivalents; *b*, nucleus containing a heteromorphic pair, a quadrivalent and seven bivalents

Table 1

Male plant No.	No. of nuclei without quadrivalent	No. of nuclei with quadrivalent
15	13	0
OL 45	1	0
321	5	11
OR 80	6	1
RY 83	2	1
OB 79	1	2

Table 1), and in view of Jacobsen's work it seems likely that the heteromorphic pair consists of the sex chromosomes, in which case the quadrivalent must be an association of autosomes.

These observations raise doubts concerning the identity of Sinoto's and Ono's quadrivalents. The only evidence to suggest that they include the sex chromosomes is Ono's work on var. *cordifolius*. Since he has reported both quadrivalent and homotype chromosomes in wild Canadian male plants, his observation of a similar difference between male and female plants of var. *cordifolius* is not conclusive evidence that this difference is related to sex determination. Examination of meiosis in males of var. *cordifolius* by Dark (unpublished work) showed that of 66 nuclei recorded only 45 contained trivalent or quadrivalent associations, and since Ono does not indicate the number of *cordifolius* nuclei studied, this raises further doubts as to the validity of his conclusions.

Even if the quadrivalent of var. *cordifolius* is accepted as being a sex chromosome complex, it is clear from the results reported here that there is no justification for making a similar assumption about quadrivalents found in other strains, in the absence of supporting evidence.

A Chromosome Count in *Schizaea*

The Schizaeaceae are a very ancient family of ferns, with only four very distinct genera still living. In view of their great antiquity, the cytology of these plants is of considerable interest for fern phylogeny. Manton[1] has recorded chromosome numbers in two of the four genera, namely, $n = 38$ and 76 in *Anemia*, and $n = 29$ and 30 in *Lygodium*. No information is available for *Mohria*, nor, until now, for *Schizaea*. The extreme difficulty of maintaining any of the known species of *Schizaea* in cultivation is no doubt a principal reason for this omission.

During a year's stay in New Zealand, during the tenure of a New Zealand National Research Fellowship, an opportunity arose on two occasions to obtain meiotic fixings from wild material of *Schizaea asperula* Wakefield[2] (formerly included in *S. bifida* Willdenow). The localities were Waikumete, near Auckland, and West Wanganui Inlet (West Haven), N.-W. Nelson, South Island. The same chromosome number was obtained for both localities. An example of diakinesis is illustrated in Fig. 1, showing unequivocally that $n = 77$.

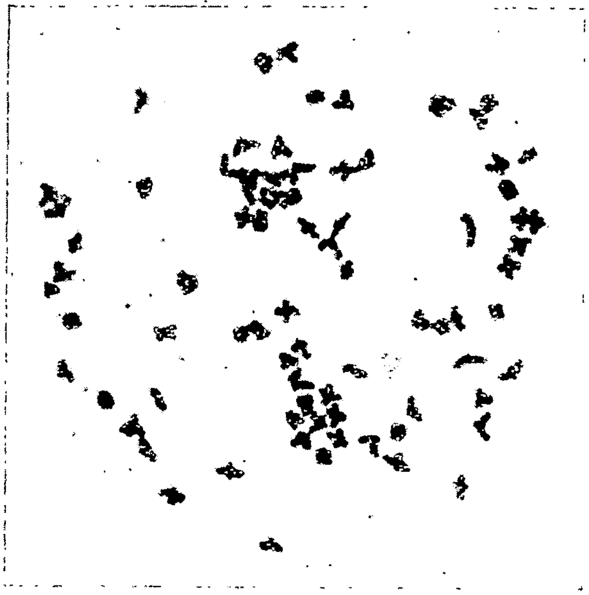

Fig. 1. Diakinesis in *Schizaea asperula* from West Wanganui Inlet, N.-W. Nelson, New Zealand, with $n = 77$. (× 750)

It is premature to discuss the interpretation of this number except to point out that there need not be any direct relationship to the $n = 76$ found in one species of *Anemia*.

A more detailed description of this investigation will be published elsewhere, together with an account of work on the taxonomy and distribution of *Schizaea* in New Zealand.

Pseudofertilization in the Genus *Lumbricillus* (Enchytraeidae)

Natural populations of the common enchytraeid worm *Lumbricillus lineatus* Müll., occurring in decaying seaweed, contain diploid ($2n = 26$) and triploid ($3n = 39$) individuals. The Enchytraeidae are normally hermaphrodite but the triploid form of *L. lineatus* reproduces parthenogenetically and is distinguishable from the diploid type by the absence of seminal vesicles. Spermatogenesis in the parthenogenetic form does not proceed beyond the spermatid stage and no mature spermatozoa are produced[1]. In spite of this, the spermathecæ of triploid worms from natural populations always contain spermatozoa. Experiments were designed to determine the origin of these spermatozoa as well as their possible role in the activation of cleavage in triploid eggs. The triploid form will be referred to as *L. lineatus* 3 × and the diploid as *L. lineatus* 2 ×.

Cultures were set up containing either *L. lineatus* 3 × alone, or together with related species of the genus *Lumbricillus* also occurring in decaying seaweed. The different combinations used are shown in Table 1 (col. 1); each culture contained at least ten worms of each species. All *L. lineatus* 3 × individuals were isolated at a sexually immature stage, before they had copulated. The cultures were examined at frequent intervals for the presence of spermatozoa in the spermathecæ of *L. lineatus* 3 × (col. 2). The cocoon production of *L. lineatus* 3 ×

Table 1. PRESENCE OF SPERMATOZOA IN THE SPERMATHECÆ, COCOON PRODUCTION AND EMBRYO DEVELOPMENT IN *Lumbricillus lineatus* 3 × IN PURE AND MIXED CULTURES

Culture combinations	Spermatozoa present in spermathecæ	Cocoons laid, cleavage beginning	Cocoons hatching, cleavage completed
L. lineatus 3 ×	—	+	—
L. lineatus 3 × *L. lineatus* 2 ×	+	+	+
L. lineatus 3 × *L. rivalis*	—	+	—
L. lineatus 3 × *L. pagenstecheri*	—	+	—
L. lineatus 3 × *L. viridis*	—	+	—

and the development of the embryos were also followed (cols. 3 and 4).

Table 1 shows that spermatozoa were present in the spermathecæ of *L. lineatus* 3 × only in the *L. lineatus* 3 × /2 × cultures, whereas none of the other species considered (col. 1) provided spermatozoa to *L. lineatus* 3 ×. Hence the triploid parthenogenetic form can only copulate with the closely related diploid species. The experiments also prove that spermatozoa from *L. lineatus* 2 × are necessary for the successful development of the eggs of *L. lineatus* 3 × (col. 4), since only in the 3 × /2 × cultures did the embryos of *L. lineatus* 3 × hatch. In all the other combinations development was arrested before the typical dorso-ventral curvature[2] of the embryo had occurred. It has been definitely established that *L. lineatus* 3 × reproduces parthenogenetically[1] and, although spermatozoa from *L. lineatus* 2 × are necessary for normal cleavage of the eggs, they do not contribute chromosomes to the 3 × nuclei. The exact role of the spermatozoa remains to be determined and will be dealt with in a later paper.

The observed phenomena represent a special case of pseudofertilization in which spermatozoa from a sexual diploid hermaphrodite species are necessary for the normal development of the eggs of a parthenogenetic relative. Thus although the triploid form has a parthenogenetic reproductive mechanism and is genetically isolated, it cannot exist independently of the diploid species. The term 'obligatory co-existence' gives an adequate description of this relationship. A similar case has been observed in the spider beetles *Ptinus latro* ($3n = 27$) and *P. hirtellus* ($2n = 18$)[3].

While it is recognized that the situation described presents a problem in nomenclature, the two forms will be provisionally referred to as subspecies of *L. lineatus*. Thus the name *Lumbricillus lineatus* ssp. *lineatus* is proposed for the diploid form and, because of the absence of seminal vesicles, the name *Lumbricillus lineatus* ssp. *avesiculatus* is proposed for the triploid form. The nomenclatural problem will be discussed further in a later paper.

The work is being financed by a grant from the Danish State Research Foundation (B. C.) and a University of Wales Research Fellowship (F. B. O'C.).

Records of the Group Pogonophora in the Skagerrak

UNTIL recently, specimens of the strange deep-sea animals belonging to the group Pogonophora were known only from the Pacific. The first records were from Indonesia, and later on large samples were found by the Russians in the north-western part of the Pacific, and several species were described from this area. In 1956 I described some new finds from the eastern part of the Pacific, namely, from the Gulf of Panama, where they were taken by the *Galathea*[1]. At the same time a description appeared of a new species, *Siboglinum ekmani*, by G. Jägersten[2]. This species was found in the Skagerrak, many miles from the earlier habitats. It was taken during the Skagerrak Expedition in 1933, but not identified until recently.

In April 1957 I had the opportunity of joining the Danish Fisheries Investigations ship, s.s. *Dana*, in the same area in the Skagerrak, where *Siboglinum ekmani* had been found. At the deepest part of the Skagerrak off the south coast of Norway, 700 m. below the surface, we obtained fairly large quantities of the same species. The tubes are small, having a

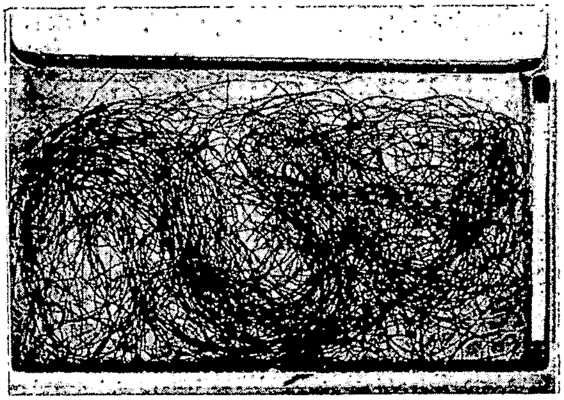

Fig. 1

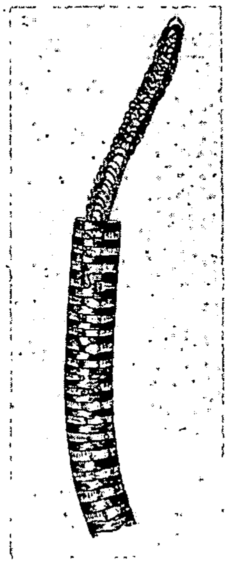

Fig. 2

diameter of 0·15 mm. and a length of about 100 mm. They are hair-like, and appear like small threads of algae or threads from the trawl (Fig. 1). But when they are seen in the microscope they are recognized at once, the structure being very characteristic (Fig. 2). The distribution of this species is probably wider than indicated by my finds. The animals seem to prefer cold water, as all the records in the world are from deep water with low temperatures. In the deep part of the Skagerrak the temperatures are about 5° C. throughout the year.

British Pea-crabs (*Pinnotheres*)

The adult male and female of *Pinnotheres pisum* (Pennant) are unlike in appearance, the male being thick-shelled, with a conspicuous colour pattern, the walking legs flattened and bearing fringes of long plumose hairs, enabling it to swim. The adult female is considerably larger, thin-shelled, generally without a colour pattern and without swimming hairs.

It was formerly considered that the males of *P. pisum*, young and adult, were normally of one form, although a few so-called abnormal crabs resembling the female in consistency and lack of colour had been found[1,2]. Further work has made it clear that the male occurs in two main forms. The one which approaches the young stage-II female in appearance is seasonal in occurrence, being found mostly in the summer, June–August inclusive in south-west England, that is, during the moulting season of the male and when young crabs occur in mussels, and rarely at other times. It therefore appears that males occur in the thin-shelled form during periods of rapid growth.

Rearing of a number of males within *Mytilus*, and the moulting of others soon after their arrival in the laboratory, has shown that the male repeatedly changes from one form to the other. A curious fact is that not once did the thick-shelled male moult into the same form, one to three thin-shelled forms intervening. With few exceptions the crabs remained for a longer time in the thick-shelled than in the thin-shelled form: in the former condition they were restless, frequently leaving and re-entering their hosts, while in the latter they never did so, being unable to swim.

The thin-shelled male has a normal male abdomen, only slightly wider in relation to the width of the thorax than that of the thick-shelled male. Thick-shelled males have been found at a carapace width of 1·4–7·6 mm.; thin-shelled males 1·9–6·3 mm.

Males resembling the female in consistency and lack of colour have been recorded in *P. maculatus* by Rathbun[3] and in *P. ostreum* by Stauber[4]. In *P. pinnotheres* (L.) (= *veterum* Bosc.), in which there is no comparable sexual dimorphism, I have found only one type of male, although eight have been reared in the laboratory—one for 22 months—through as many as five moults. In this species the young adult female is capable of swimming.

The juvenile females of *P. pisum* resembling hard-shelled males have been found to pass through several growth-stages to reach the adult[1,2]. These stages have now been followed in each of four crabs with initial carapace widths of 3–4 mm., which lived for up to two years before being killed: two spawned.

All male-like females were termed stage I: this did not imply that they are the first crab stage[2]. The smallest *P. pisum*, a male, taken from *Mytilus*, had a carapace width of 1·4 mm. and this is probably not less than the third crab stage, for the megalopa has a carapace width of about 0·57 mm.[5]. Stage I females have been found with a carapace width of up to 4·9 mm., so it is evident that growth can occur with little or no widening of the abdomen. The smallest stage-II female with abdomen appreciably wider than that of the male had a carapace width of 2·1 mm. It appears that during growth, without or with only slight widening of the abdomen, the crab does not remain thick-shelled, but that one or more periods may intervene during which it is stage II in consistency, in lack of colour and of swimming hair, but with narrow abdomen. During this time the pleopods remain as little developed as in the thick-shelled stage I[2]. That these crabs are not the result of laboratory conditions is proved by their occurrence in the wild. Those few reared had empty spermathecæ.

In addition to the rearing of both *P. pisum* and *P. pinnotheres* in hosts in the laboratory, a population of *P. pisum* in the Camel Estuary, north Cornwall, was sampled approximately monthly for two years, and populations from other localities less frequently. It was found that the male *P. pisum* reaches sexual maturity at a carapace width of about 2·0 mm.: copulation is precocious, a female of 1·75 mm. carapace width being found with full spermathecæ, while the smallest ovigerous female had a carapace width of 6·5 mm.

In *P. pisum* the main spawning months in south-west England are May–August; spawning can occur three days after hatching of the previous brood, and it is probable that a crab spawns several times during the season. The main moulting season of the male is June–August, that of the female June–October.

A full account of this work and of other aspects of the biology of *P. pisum* and *P. pinnotheres* will be published elsewhere.

The Cromer Forest Bed: Preglacial or Interglacial?

Now that the detailed palæobotanical account of the interglacial deposits at Bobbitshole, Ipswich, by Dr. R. G. West[1], of the University Sub-department of Quaternary Research, Cambridge, has appeared we are better able to appreciate the magnitude of our debt to him and to their finder, Mr. H. E. P. Spencer, of the Ipswich Museum. Correlation of East Anglian and Continental late Pleistocene events has been thereby substantially aided, but in the concluding section of the paper a statement re-appears about the correlation of an older phase which is difficult to reconcile with our records of East Anglian stratigraphy. The statement is that, in the opinion of the well-known authority, Prof. P. Woldstedt[2], the palynology of the Cromer Forest Bed series shows that it "was formed in the oldest (Cromerian) interglacial period in East Anglia". Dr. West has, apparently independently, reached the same conclusion. It therefore becomes desirable to direct attention to some of the geological difficulties that arise from this interpretation.

The occurrence of an interglacial phase implies that of a preceding glaciation, but no moraines or till belonging to such are known in East Anglia before the Cromer Forest Bed was formed. Admittedly, all traces may have been removed in the course of a subsequent glaciation, or completely covered and not revealed by borings and excavations since. In that event, we are driven to utilize the evidence from neighbouring areas, for example, northern Europe. Before referring to the latter, however, I may note that the East Anglian shelly sands and gravels, known as Crag, which are in the main (if not wholly) older than the Cromer Forest Bed, furnish no sound evidence of climatic change other than a gradual cooling (shown by the Mollusca) and the possible transport of erratics by icebergs from the north. The implications of a Crag glaciation were reviewed in detail some years ago[3], when efforts were made to resolve certain difficulties that had arisen in the linking up of the industries of early man with well-established glacial and interglacial events; but the assumption of an early Crag glaciation seemed to increase rather than lessen the difficulties.

The succession that has served us reasonably well as a standard in the east of England for many years past is set out in Table 1 (in which I have retained the older nomenclature as well as the newer terms because it remains more appropriate in several respects). The various early human industries can be fitted into the scheme (allowing for time occupied in migration) without excessive strain.

Table 1

Hunstanton Boulder Clay (Newer Drift) = Warthe, ? Weichsel = Würm
  Interglacial (Bobbitshole, etc.) = Eemian in part
Upper Chalky Drift (Gipping Boulder Clay) = Saale = Riss
  Interglacial (Hoxne, etc.) = Elster/Saale = Mindel/Riss
Chalky-Jurassic Boulder Clay (Lowestoft Boulder Clay) = Elster = Mindel
  Interglacial ("Middle" glacial, Corton Beds, etc.) = ? Günz/Mindel
North Sea Drift (Norwich Brickearth, Cromer Tills ?) = ? Donau, ? Günz 1, ? Günz 2
  Cromer Forest Bed series
  Pleistocene shelly sands (Crags)

The succession recorded in the lower half of the table is based on the evidence from inland and coastal exposures in northern and eastern Norfolk. At Corton, north of Lowestoft, for example, a peaty bed at beach-level, tentatively referred by Clement Reid to the Cromer Forest Bed, is seen to be succeeded by the Norwich brick-earth, then by the sands and gravels termed by D. F. W. Baden-Powell the Corton Beds (in which, in the nearby Flegg Hundred, S. V. Wood, jun., found molluscan assemblages of mixed character), and finally by the Chalky-Jurassic Boulder Clay. On the northern coast of Norfolk the Cromer Forest Bed visibly underlies the Cromer Till, which in turn underlies sands containing a shelly fauna and identified by Baden-Powell with his Corton Beds. The interglacial phase here represented was marked by widespread weathering and erosion of the Norwich brick-earth and the overlying sands and gravels, the major valley-systems of the region being then brought into existence.

In passing, I may note that if the Cromer Tills come to be regarded as a facies of, not the North Sea Drift, but the Chalky-Jurassic Boulder Clay, the Cromer Forest Bed may prove to belong to this interglacial interval. In that event, however, the peaty bed at Corton cannot be the Cromer Forest Bed. Further investigations of this peaty bed throughout eastern Norfolk are thus highly desirable. Although we possess much information about the fossil contents of the Cromer Forest Bed at its type locality, we know strikingly little about its areal distribution or about the extent in space and time of the unconformity that underlies it.

Evidence from the Continent in support of the view that the Cromer Forest Bed belongs to the oldest interglacial is far from good. Geologists have hitherto been unable to agree that any trace of the earliest (Günz) glaciation of the Alps occurs in the area of northern Europe extending from the Netherlands to the U.S.S.R. While some authorities still doubt the existence of the Günz in the Alpine area itself, others see in the pre-Mindel moraines and other glacial deposits of the peripheral area the relics of separate glaciations which have been termed[4] the Donau, Günz 1 and Günz 2. Early interglacial or interstadial deposits have in places yielded pollen-bearing beds, but the stratigraphical relationships are not sufficiently precise to enable geological correlation to be established. Baden-Powell's comparison[5] of the shelly faunas of the Mediterranean Pleistocene marine stages (terraces, etc.) with those in East Anglia favours the view that the oldest interglacial follows rather than precedes the North Sea Drift glaciation. With considerable skill he has diagnosed the Corton Beds fauna as the climatic equivalent of the Tyrrhenian stage of the Mediterranean under a modified Pleistocene isothermal distribution. This phase followed the first cold stage in that area—the Sicilian—which he would correlate with the earliest glaciation of northern Europe.

Until the figures for absolute age obtained by tests for radioactivity become available (and they are slow to accumulate), we rely for correlation on the evidence provided by fossil groups such as the Mammalia, Mollusca and plants, among others; also, in order that the risk of homotaxial relationships being mistaken for contemporaneity may be reduced to a minimum, we hope the lines of evidence will converge. The classification of the East Anglian Pleistocene set out above is doubtless over-simplified by the omission of stadia and interstadia, but there seems little advantage in altering the status (for example, glaciation into stadial ice-advance, or *vice versa*) of our well-individualized events, even for the time being. The alternative is to await new evidence. Until some of the difficulties outlined in the foregoing have been met, it would appear premature to assign the Cromer Forest Bed to the oldest interglacial period in East Anglia.

FORTHCOMING EVENTS

Monday, April 14

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Mr. G. W. Kirkland, M.B.E.: "Pre-stressed Concrete". (First of three Cantor Lectures. Further Lectures on April 21 and 28.)

Society for Visiting Scientists (at 5 Old Burlington Street, London, W.1), at 7.30 p.m.—Discussion Meeting on "Personality". Chairman: Prof. C. A. Mace. Speakers: Prof. Marc Klein, Dr. W. Mays and Dr. J. D. Sutherland.

Tuesday, April 15

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

Institution of Electrical Engineers, Measurement and Utilization Sections (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. E. Bradshaw, Mr. M. Wagstaff and Mr. F. Cooke: "A Train Performance Computer"; Mr. J. F. Meredith and Mr. E. A. Freeman: "The Stimulation of Distributed-Parameter Systems, with particular reference to Process Control Problems"; Dr. J. L. Douce and Dr. J. C. West: "A Magnetic-Drum Store for Analogue Computing".

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Mr. E. G. Walker: "Factors in the Design of Airborne Doppler Navigation Equipment".

Tuesday, April 15—Thursday, April 17

Society of Chemical Industry, Plastics and Polymer Group (in the William Beveridge Hall, Senate House, University of London, London, W.C.1)—Silver Jubilee Symposium on "The Physical Properties of Polymers".

Wednesday, April 16

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. W. E. Tremlett: "The Structure of the Lower Palæozoic Rocks of the Arklow District (Ireland)".

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Discussion on "Some Problems in the Measurement of Price Changes, with special reference to the Cost of Living" opened by Dr. S. J. Prais.

Institution of Electrical Engineers, Supply Section (joint meeting with the British Nuclear Energy Conference, at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. K. L. Stretch: "Operational Experience—Calder Hall".

Society for Analytical Chemistry, Biological Methods Group (at "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m.—Discussion on "The Mathematics of Sterility Testing", introduced by Mr. D. Maxwell Bryce.

Society of Chemical Industry, Corrosion Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Annual General Meeting. Dr. W. H. J. Vernon: "Corrosion Research and its Industrial Background" (Spring Lecture).

Thursday, April 17

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. P. G. Safeman and Sir Geoffrey Taylor, F.R.S.: "The Penetration of a Fluid into a Porous Medium or a Hele-Shaw Cell containing a More Viscous Liquid"; Mr. C. Kemball and Mr. C. T. H. Stoddart: "The Catalytic Hydrogen Reduction and Deuterium Exchange of *cyclo*pentanone on Evaporated Metallic Films and some Observation on *cyclo*hexanone".

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. E. O. Lilge, Mr. T. E. Fregren and Mr. G. R. Purdy: "Apparent Viscosities of Heavy Media and the Driessen Cone"; Mr. H. H. Fraser: "Scientific Management Principles Applied to West African Mining".

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. J. G. Clunie: "Meromorphic Schlicht Functions".

Institution of Mechanical Engineers, Applied Mechanics Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m. Discussion on "Training in Engineering Design".

Society of Chemical Industry, Road and Building Materials Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. R. J. Schaffer: "The Preservation of Building Stone".

Royal Photographic Society (at 16 Princes Gate, London, S.W.7), at 7 p.m.—Mr. J. B. Collins: "Some Applications of Photography to Lighting Research".

Thursday, April 17—Friday, April 18

British Association for the Advancement of Science (in the Hall of the Royal Geographical Society, Kensington Gore, London, S.W.7), at 10 a.m. daily—Conference on "Science in Schools".

Friday, April 18

Institute of Physics, Non-Destructive Testing Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Meeting on "High Speed Radiography". Mr. R. F. Thumwood: "Tubes and Mechanisms"; Mr. B. Meakin: "Circuits and Evaluation".

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Annual General Meeting.

Society of Chemical Industry, Fine Chemicals Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. E. G. E. Hawkins: "Organic Peroxides and their Industrial Uses".

Friday, April 18—Saturday, April 19

Biochemical Society (at University College, Gower Street, London, W.C.1), at 10.45 a.m. on Friday and 10.30 a.m. on Saturday—Annual General Meeting.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Research Worker in Rumen Biochemistry (Scientific Officer or Senior Scientific Officer grade)—The Secretary, Institute of Animal Physiology, Agricultural Research Council, Babraham, Cambridge (April 17).

Lecturer in Geology; a Lecturer in Mathematics; a Senior Lecturer or Lecturer and an Assistant in Natural Philosophy; a Senior Lecturer or Lecturer and an Assistant in Experimental Physics; and a Lecturer and an Assistant in Theoretical Physics—The Secretary, The University, Aberdeen (April 18).

Lecturer (with a good honours degree in botany, a special interest in mycology and able to teach botany to degree standard and also industrial mycology) in Botany—The Principal, Wigan and District Mining and Technical College, Wigan (April 18).

Assistant Lecturer (science graduate or medically qualified) in Pharmacology in the Faculty of Medicine—The Registrar, The University, Manchester 13 (April 19).

Biochemist (Basic grade), to work mainly on problems of calcium and phosphorus metabolism in the Metabolic Ward Laboratories—The Administrator and Secretary, University College Hospital, Gower Street, London, W.C.1 (April 19).

Scientific Officer (with a good honours degree in zoology, some research experience in invertebrate physiology, and an interest in ecology) at Merlewood Research Station, Grange-over-Sands, Lancashire, to join a team studying fauna and woodland soils—The Nature Conservancy (E), 19 Belgrave Square, London, S.W.1 (April 21).

Assistant Lecturer, Grade B (with good academic qualifications and special experience in physical chemistry), in Chemistry—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (April 25).

Assistant Lecturer (man or woman) in Botany—The Principal, Royal Holloway College, Englefield Green, Surrey (April 25).

Assistant Lecturer or Lecturer in the Department of Zoology—The Registrar, The University, Liverpool (April 26).

Fellow in the Department of Geophysics, Research School of Physical Sciences, Australian National University, Canberra, to assist in the Department's programme of work on rock magnetism—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (*Australia*, April 30).

Lecturer (medical graduate, with lecturing experience and practical experience in virology and bacteriology) in Bacteriology—The Registrar, The University, Bristol (April 30).

Turner and Newall Research Fellows in Engineering, Inorganic Chemistry, Physics and allied subjects—The Registrar, The University, Manchester (April 30).

Assistant Lecturer or Lecturer in Physics—The Secretary, The University, Exeter (May 3).

Assistant Lecturer or Lecturer (specially qualified in plant biochemistry and/or cell physiology) in the Department of Botany—The Registrar, University College, Singleton Park, Swansea (May 3).

Lecturer in the Department of Metallurgy—The Registrar, The University, Liverpool (May 3).

Research Demonstrator in Botany—The Registrar, University College, Singleton Park, Swansea (May 3).

Research Fellow in the Department of Mathematical Physics—The Registrar, The University, Birmingham 15 (May 5).

Reader in Experimental Physics at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1 (May 7).

Reader in Statistics at the London School of Economics and Political Science—The Academic Registrar, University of London Senate House, London, W.C.1 (May 9).

Lecturer in Biochemistry; an Assistant in Biochemistry; and an Assistant in Logic and Metaphysics and Moral Philosophy in St. Salvator's College—Joint Clerk to the University Court, College Gate, St. Andrews (May 10).

Lecturer in Microbiology in the Department of Brewing and Applied Biochemistry—The Principal, Heriot-Watt College, Edinburgh (May 15).

Research Students or Assistants for work in the Physical Chemistry Department on the mechanism of reactions of biological interest—The Secretary of University Court, The University, Glasgow (May 15).

Senior Lecturer in Zoology at Makerere College (University College of East Africa)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (May 16).

Senior Research Fellow (preferably theoretical physicist) in Physics at the University of New England, Australia, to undertake a programme of experimental or theoretical research, preferably but not necessarily on the field of ionization and discharge physics or of solid state physics—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, May 26).

Chair of Geography in the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (May 30).

Chair of Pharmaceutics in the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (May 31).

Lecturer in Psychology at Canberra University College, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, May 31).

Scientific Assistant (preferably with a Ph.D. in biochemistry and some experience with proteins) in the Department of Pathology, for research work on intrinsic factor—The Registrar, King's College (University of Durham), Newcastle-upon-Tyne.

Senior Lecturer or Lecturer in Physics at the University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

Senior Lecturer (with at least three years experience of teaching to degree standard and also preferably a higher degree) in Zoology—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

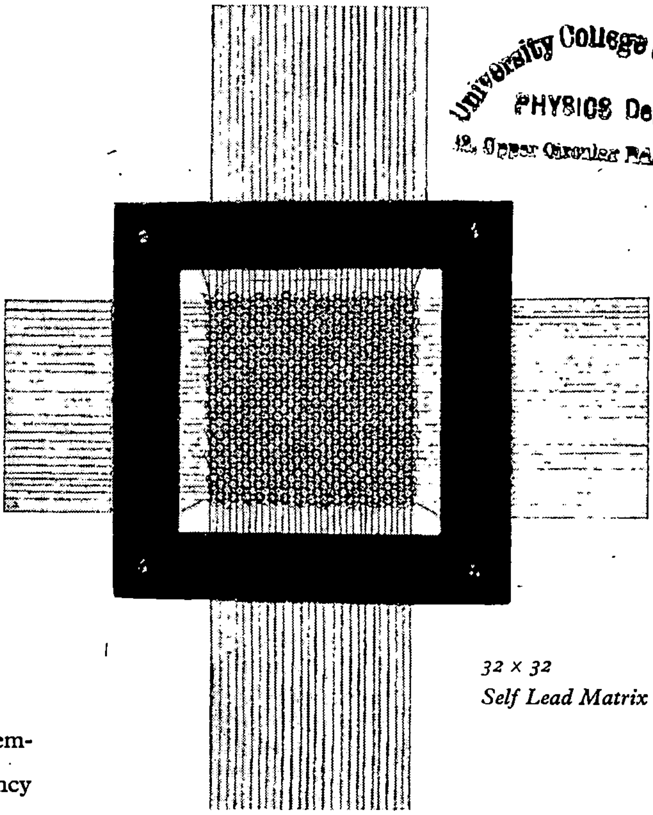
Formula for Computer Efficiency...

'FERRAMIC' FERRITE CORES AND ASSEMBLIES



32 x 32
Self Lead Matrix

Plessey 'Ferramic' Square Loop Ferrite Cores and Assemblies ease design problems and ensure maximum efficiency in high speed digital computers. They are available in two types of graded material—designated S1, and S3.

'Ferramic' S1 material is notable for the tight limits to which top-grade cores are 100% tested, for high operating speeds, high output voltages on switching, and low values of noise voltage output.

'Ferramic' S3 material obviates the need for ultra-small cores where lower operating current is used and where the high speeds of S1 material are not required.

Cores in 'Ferramic' S1 and S3 are now available in *eight sizes* ranging from 0.050″ to 0.375″ o.d.

Matrix Stores These can be made to customers' designs, or Plessey preferred patterns can be supplied. Plessey specialise in transistor driven types using 0.050″ o.d. cores.

Transfluxors Multi-aperture cores are available for flip-flop circuits, non-destructive read-out stores and many other applications.

Logical and Switching Units Available in S1 or S3 material as required by customers. As many as ten windings with a total of 400 turns can be provided on 0.120″ o.d. cores. All units are encapsulated in Polyester or epoxy resin with terminations as required.

The Company's Technical Representatives will gladly discuss Design Engineers' requirements and invite applications for samples, and of course publications:- Data Sheet 6044 ('Ferramic' S1 Square Loop Ferrites); Advance Information Sheet 936 ('Ferramic' S3 Square Loop Ferrites); and Advance Information Sheet 938 (Magnetic Memory Planes).

LECTURES AND COURSES

UNIVERSITY OF EDINBURGH

Principal: Sir Edward Appleton, G.B.E., K.C.B., D.Sc., F.R.S.

DIPLOMA IN ELECTRONICS AND RADIO

The one year Postgraduate Diploma Course in Electronics and Radio will commence on October 7, 1958, and will provide specialized training for those wishing to proceed to research in this field, or to employment in industrial organizations. Applicants should hold an honours degree in electrical engineering, mathematics or physics. The main lecture courses are in network theory, principles of value and transistor circuits, transmission and radiation theory, and particles in fields. Laboratory and field work will be arranged to support the lecture courses. A limited number of grants can be made available for suitable candidates.

Further particulars and application forms can be obtained from the Secretary to the University, University of Edinburgh, Old College, South Bridge, Edinburgh, 8.

CHARLES H. STEWART,
Secretary to the University.

UNIVERSITY OF SHEFFIELD

POSTGRADUATE SCHOOL IN MINING

Facilities are available for graduates in science or engineering and similarly qualified persons to undertake research into scientific problems related to mining.

A special one year course of instruction leading to a Postgraduate Diploma in Mining will begin in October, 1958. Entry to this is not confined to graduates.

Full particulars from the Director, Postgraduate School in Mining, University of Sheffield, St. George's Square, Sheffield, 1.

UNIVERSITY OF LEEDS

(Electronic Computing Laboratory)
Vacation Course in
PROGRAM DESIGN FOR
AUTOMATIC DIGITAL COMPUTING
MACHINES
July 7-18, 1958
Full details on application to
The Secretary, Department of Extra-Mural
Studies, The University, Leeds, 2.

NORTH STAFFORDSHIRE TECHNICAL COLLEGE

STOKE-ON-TRENT

Principal: H. W. Webb, O.B.E., D.Sc., F.R.I.C., M.I.Chem.E., F.I.Ceram.

COLLEGE OF CERAMICS

COURSE ON ELECTRICAL AND OTHER TECHNICAL CERAMICS

There will be a four-day course of lectures on the above subject at the College of Ceramics, North Staffordshire Technical College, Stoke-on-Trent, from Tuesday, June 3 to Friday, June 6 inclusive, from 10 am. to 1 p.m., and from 2 p.m. to 5 p.m. each day. Specialists in the various fields will summarize the present position regarding porcelain, steatite, alumina, borides, carbides and nitrides, cermets, ferroelectrics, ferromagnetics and semi-conductors. The fee for the course will be £2. Further particulars may be obtained from the Principal, North Staffordshire Technical College, Stoke-on-Trent.

H. DIBDEN,
Clerk to the Governors.

OFFICIAL APPOINTMENTS

RESEARCH COUNCIL OF ALBERTA

POSTDOCTORATE FELLOWSHIPS IN CHEMISTRY

Applications are invited for postdoctorate fellowships for fundamental research in the following fields: "Electron Paramagnetic Resonance" with emphasis on free radicals in solution including the oxidative polymerization of phenols; "Sorption of Gases" and the physical properties of the sorbed phase; "Kinetics of Gas Phase Reactions" and kinetic isotope effects. The latest in modern instrumentation will be available for these studies. Applicants should have, or expect to have, a Ph.D. or equivalent degree before taking up the award. The annual stipend, $3,700, single, or $4,500, married, is tax free; an allowance for travel will also be made. Awards are tenable for one year and may be renewed for one additional year.

Inquiries and a brief summary of interests and experience should be addressed to the Secretary, Research Council of Alberta, Edmonton, Alberta.

UNIVERSITY COLLEGE OF SWANSEA

Applications are invited for either an Assistant Lectureship or a Lectureship in the Department of Botany from October 1, 1958. Candidates should be specially qualified in plant biochemistry and/or cell physiology. Salaries: Assistant Lectureship, £700 to £850 per annum. Lectureship, £900 to £1,650 per annum. Commencing salary in each case will be at a point on the appropriate scale according to age, qualifications and experience. Membership of the F.S.S.U. and children's allowance scheme.

Further particulars may be obtained from the Registrar, University College, Singleton Park, Swansea, to whom applications (six copies) must be sent by May 3, 1958.

ROYAL HOLLOWAY COLLEGE

UNIVERSITY OF LONDON

ASSISTANT LECTURER IN BOTANY

The Council invites applications for an Assistant Lectureship in botany tenable from October 1, 1958. The post is open to a man or a woman. The salary will be on the scale approved by the Senate of the University of London, according to age and experience, with a minimum of £700 plus £60 London allowance a year, non-resident, or, for a resident woman, a minimum of £500 plus £60 London allowance a year, together with board and residence. Women are usually expected to be resident. Applications are required by April 25, 1958, if possible.

Full particulars may be obtained from the Principal, Royal Holloway College, Englefield Green, Surrey.

UNIVERSITY OF MANCHESTER

Applications are invited from graduates for the post of Assistant Lecturer in Psychology. Candidates should have special interests or training in experimental and statistical psychology. Applications will be considered from candidates who intend to graduate in 1958. Salary on a scale £700 to £850 per annum with membership of the F.S.S.U. and children's allowance scheme.

Applications should be sent not later than April 19, 1958, to the Registrar, the University, Manchester, 13, from whom forms of application and further particulars may be obtained.

UNIVERSITY COLLEGE OF SWANSEA

Applications are invited for the following appointments to be made under the terms of a Nuffield Foundation Grant to Professor H. E. Street and tenable in the Department of Botany. To undertake a survey of the nutritive requirements of the excised roots of different species and varieties; a Research Fellowship (£800 per annum,) and a Research Assistantship (£400 per annum). Successful candidates will be expected to take up their duties on October 1, 1958.

Full particulars of these posts may be obtained from the Registrar, University College, Singleton Park, Swansea, by whom applications must be received by Saturday, May 3, 1958.

A.E.R.E. HARWELL *have a vacancy for a* **SENIOR RESEARCH SCIENTIST** *in Chemical Engineering Division*

The requirement is for a professional man of academic bent, with keen interest in furthering fundamental study of unit operations in chemical engineering, to develop new techniques and improve design methods.

Personal qualities of leadership and an established professional reputation are required with positive command of modern treatments of mass and energy transfer, thermo-dynamics, and kinetics in chemical engineering.

The laboratories of the Chemical Engineering Division provide unrivalled facilities for research of a high standard in a unique scientific environment.

Salary in the range £2,100 to £3,150

Send a postcard to Group Recruitment Officer (1108Y/34), A.E.R.E., Harwell, Didcot, Berks, for further details and application form.

UNIVERSITY COLLEGE OF SWANSEA

Applications are invited for the post of Research Demonstrator in Botany from October 1, 1958. Salary £625 per annum. The appointed person will be expected to engage in experimental research in botany.

Further particulars may be obtained from the Registrar, University College, Singleton Park, Swansea, by whom applications must be received by Saturday, May 3, 1958.

UNIVERSITY OF MANCHESTER

Applications are invited for the post of Assistant Lecturer in Mathematical Statistics. The salary is on the scale £700 to £850 per annum, with membership of the F.S.S.U. and children's allowance scheme.

Applications should be sent not later than April 18, 1958, to the Registrar, the University, Manchester, 13, from whom further particulars and forms of application may be obtained.

UNIVERSITY OF LIVERPOOL

Applications are invited for the post of Assistant Lecturer or Lecturer in the Department of Zoology. The salary range for an Assistant Lecturer is £700 to £850 per annum; the initial salary for a Lecturer will be within the range £900 to £1,250 per annum, according to qualifications and experience.

Applications, stating age, academic qualifications and experience, together with the names of three referees, should be received not later than April 26, 1958, by the Registrar, from whom further particulars of the conditions of appointment may be obtained.

UNIVERSITY OF SASKATCHEWAN

SASKATOON, SASK., CANADA

DEPARTMENT OF PHYSICS AND INSTITUTE OF UPPER ATMOSPHERIC PHYSICS

Studentships and Assistantships ranging in value from $1,500 to $2,100 are available for research students working towards Masters and Ph.D. degrees. Experimental and theoretical research is being carried out in the fields of upper atmospheric physics, nuclear physics, and the physics of radiation therapy.

Applications and requests for further information should be made by writing air mail to Professor B. W. Currie, Head, Physics Department, University of Saskatchewan, Saskatoon, Saskatchewan.

COUNTY BOROUGH OF STOCKPORT

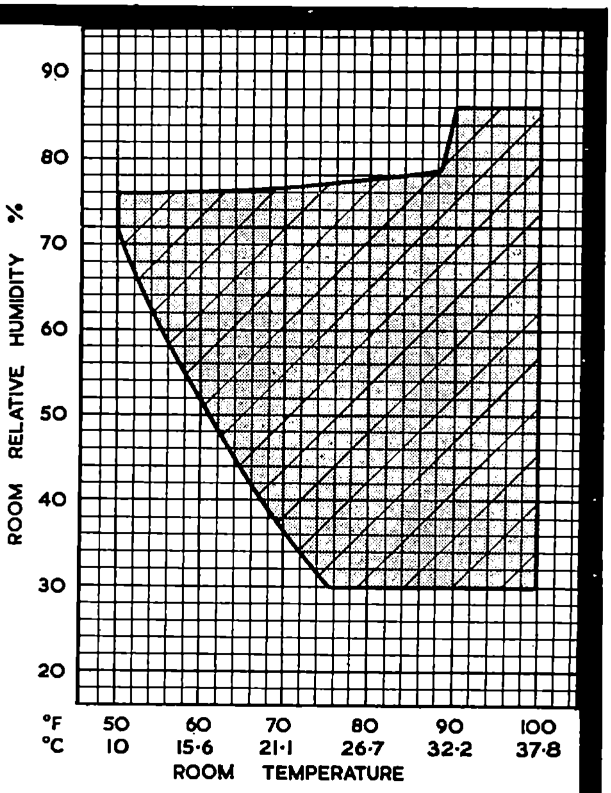
STOCKPORT COLLEGE FOR FURTHER EDUCATION

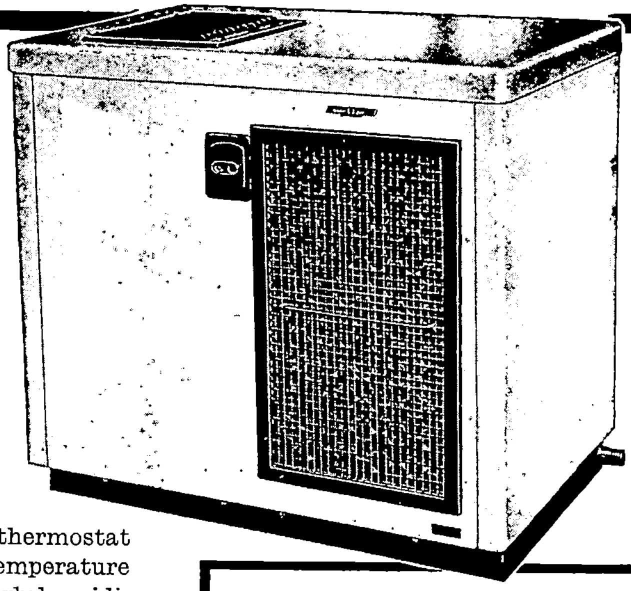
One Lecturer required (full-time) in the Science Department to teach Chemistry. Candidates must be honours graduates of a British University, and capable of teaching one branch of chemistry (preferably inorganic or analytical) to the standard of B.Sc. and final examination of Royal Institute of Chemistry. Salary, Burnham Technical Scale for Lecturer (men), £1,200 by £30 to £1,350 per annum. N.J.C. conditions.

Further particulars and application forms from Principal, Stockport College for Further Education, Wellington Road South, Stockport, to be returned by April 26, 1958.

ROYAL NAVAL SCIENTIFIC SERVICE requires Physicists, Electronic Engineers, and Mathematicians for 25 Senior Scientific and Scientific Officer posts at establishments in London area, Baldock, Harwell, Haslemere, Poole, Greenock, and Rosyth. Also required: Mechanical Engineer for work on heat transfer problems at Harwell. Mechanical Engineer for work on fuel and lubricating oil problems in London area. Mechanical Engineer for work on gas turbine and problems in London area. Chemical Engineers for London area and Poole. Metallurgists for Rosyth and Poole. Chemists (physical and inorganic) for Poole and Baldock. Candidates must normally be natural born British subjects of natural born British parents, with at least first- or second-class honours degrees or equivalent high professional attainments. Senior Scientific Officers must have had at least three years' postgraduate experience and be 26 years of age. Salaries (men): Senior Scientific Officer, £1,190 to £1,410 Scientific Officer, £635 to £1,110 (London)—somewhat lower in provinces. Appointments are unestablished (with F.S.S.U. benefits), but opportunities may occur for those unde 32 to compete for established posts.—Forms from Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street London, S.W.1, quoting A.98/8A.

PRECISION HUMIDITY AND TEMPERATURE CONTROL to any conditions within this area





Rooms up to approximately 3,000 cu. ft. can be accurately conditioned with this air-conditioning cabinet, and conditions have been maintained within ±0.5F. and 0.75% relative humidity. The cabinet is provided with an air outlet raised above bench level. Larger units are available for special applications. The specification includes a replaceable glass silk filter for air entering the cabinet; centrifugal fan complete with belt drive fan motor and starter; cooling coil of up to 35,000 B.T.U.'s extraction per hour for reduction of either temperature or humidity; air heater with built-in high limit thermostat; room thermostat with relay to operate electric heater when temperature low, or cooling coil when temperature too high; humidistat to control humidity; evaporative humidifier.

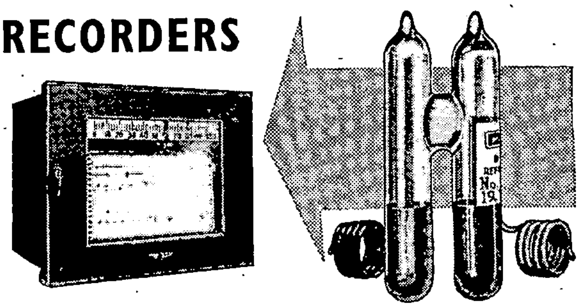
MUIRHEAD D-845 CELLS FOR RECORDERS



These cells will function under widely varying temperature conditions—be tolerant to a wide range of mounting positions — withstand rough handling and yet maintain an accurate and stable reference voltage. Mounted and unmounted types are available from stock.

E.M.F. 1·0193 volts absolute, subject to manufacturing tolerance of 0·0005 V Unmounted, 0·0002 V Mounted.
Temperature coefficient Does not exceed 5μV/°C over the range 10°—40° C.
Temperature hysteresis Negligible over the normal temperature range.
Internal resistance at 25° C. Average 800 ohms, maximum 1200 ohms.

A NEW EVAPORATION UNIT

TO MEET THE VERY HIGH MAGNIFICATION STANDARDS OF MODERN ELECTRON MICROSCOPES

Shadow-casting by vacuum evaporation is the answer to high resolution work, but the very high standards of modern microscopes demand critically accurate evaporation free from defects. THE "SPEEDIVAC" 12E6 is specially designed to meet these requirements.

★ *Fitted carbon evaporation source for carbon replica work.*

★ *Special workholder allows specimen to be accurately adjusted for height from, and inclination to, the baseplate.*

★ *Ballast tank for vibration-free running.*

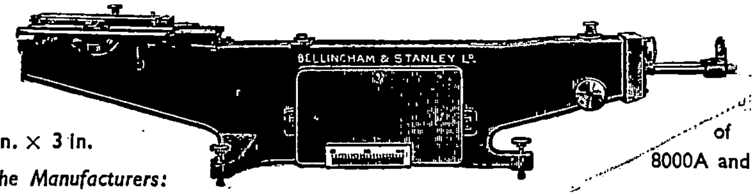
for Microscopy and Biology

PRECISION BS INSTRUMENTS

Spectrograph ***with quartz optical system***

Critical definition is obtained over the entire range of the spectrum. Size of photographic plate 12 in. × 3 in.



A larger instrument can now be supplied giving a 12 in. length of spectrum between 8000A and 2100A.

ADMINISTRATION AND DEFENCE IN A TECHNICAL AGE

"WAR, even in or especially in an atomic age, is too serious a matter to be left almost exclusively to professionals, professionals trained in an ancient art rather than in the spirit of modern science." Thus, Prof. D. W. Brogan concludes his essay on civilian and military power in the United States in "Soldiers and Governments: Nine Studies in Civil–Military Relations", edited by M. Howard (pp. 192. London: Eyre and Spottiswoode, 1957). In this essay, Prof. Brogan suggests that no aspect of American government in this age requires rethinking more urgently than the problem of the relation between the Defence Department and the American political system, and that the days are long past in which the Service departments could be left to decide and to provide for the technical needs of the defence of the United States. The technological revolution which began on the New Mexican proving grounds of Los Alamos, argues Prof. Brogan, made the constitutional conceptions of the American system largely irrelevant, and it also brought out certain weaknesses in the administrative methods of the American Service departments which are no longer tolerable and are now becoming dangerous. The most interesting point which Prof. Brogan makes in this essay, however, is in regard to education. The central power house of American offence and defence, he asserts, is no longer in the Springfield Arsenal or even in the New London Navy Yard, but in the Atomic Energy Committee. "The higher Civil servants in England who staffed the Admiralty and the War Office might not have received an adequate technical education to discuss these questions, but they knew far better than did the military bureaucrats of the Pentagon how the physicists should be handled. Oxford and Cambridge provided a better education for this function than did Annapolis or West Point."

Clearly, President Eisenhower will need to delve deep into educational issues if he is to have any permanent and far-reaching result in the attempt to secure more effective co-ordination between the three Services foreshadowed in his Budget message and give real meaning to the office of Secretary of Defence. Mr. R. Blake's essay on Great Britain in this same volume, however, should discourage any complacency over this tribute to either British organization or methods, and Mr. M. Howard's introductory essay takes us to the root of the problems which are raised both for soldiers and for governments. The dialectic between freedom and security lies at the basis of all political society, and though, as indeed in the Bermuda discussions between President Eisenhower and Mr. Macmillan, the forms of that problem may change, the problem itself is likely to be with us until society itself is dissolved.

As Mr. Blake shows in his introduction to the volume, the issues to-day are immensely more complicated—not simply the decision as to what proportion of the national income should be spent on the Armed Forces, but also what form our defences should take and, most difficult of all, what proportion of defence expenditure should be allotted to immediate needs and what to long-term development and research. The debates in Parliament over the recent report on defence have brought out sufficiently what complications and difficulties are encountered in attempting to decide for what sort of warfare we should prepare and what part should be played by each of the three Services and, as Mr. Blake is also careful to note, these problems are debated in a climate of opinion which regards the promotion of national welfare as the highest function of the State. Indeed, it could be argued that a powerful section of opinion even puts recreational interests like television before industrial or economic development.

In such a position, we do not need to enter on those far-reaching problems of the reorganization of economic life which, as Mr. Blake points out, may be involved in defence policy, to realize the fundamental importance of educational policy at all levels. What may be remarked here, however, is that there would seem to be a *prima facie* reason for those destined for commissions in the Services to be educated side by side with those taking up civil careers, at least as far as the university-level. The clearly marked trend in the post-war entry to the Services in Britain would thus seem to be in accord with a genuine need.

There are, of course, other issues involved in the message which President Eisenhower sent to Congress early in April, though what he proposed still falls short of the unification of the three Services decreed by Congress in 1947. To the scientist in Britain, possibly the most interesting proposal in that message, and also the one which is encountering most opposition, is that which would give the Secretary of Defence complete power over research and authority to distribute appropriations among the Services to meet new situations. Quite apart from any other consideration, this suggestion is only likely to be effective and perhaps workable in the appropriate educational climate.

Much the same is true of other proposals. The Chiefs of Staff were given a chairman in 1949 and they are now to be empowered to delegate most of their Service responsibilities, with the result that the unified commands, which would themselves be created by the Joint Chiefs of Staff, would be responsible to the latter as a whole, acting in the name of the Secretary of Defence. The Secretaries of the Army, Navy and Air Force would become simply assistants to the Secretary of Defence concerned with administration, supply and training for their respective Services, but with no control over overseas or field commands. Promotion to the highest ranks, from which commands would be filled, would be at the discretion of the Joint Chiefs of Staff, and the Staff Director would be named by the Secretary of Defence.

It is the educational implications of these proposals, rather than analogy or differences with British organization for defence, that are of most interest and significance in relation to the utilization of scientific and technical man-power and technological advance to-day. To end Service rivalries in the United States by giving virtually unlimited powers to the Secretary of Defence may not of itself eliminate indecision and provide the speed and flexibility needed alike in local or global war. Even if the new authority is fully in touch with the Services themselves and their problems, co-ordination will scarcely be effective unless the understanding and co-operation of the Services are secured at junior as well as senior levels. This is partly an educational problem, of encouraging junior officers to think in overall terms of defence, to be alert to recognize even minor opportunities for inter-Service co-operation at the supply-level or in matters like pay and rations. It is a question of outlook and of a new approach to many technical matters which appropriate training could assist.

President Eisenhower's initiative should stimulate constructive thinking in Britain on a number of problems which offer wide opportunities for economy in materials and man-power and for increasing the efficiency of our defence effort. Whether those opportunities are recognized and used depend a good deal on whether sufficient receptivity to new ideas is encouraged, and this in turn on the appropriateness of the training which is given both to civilians and those in the Services, and not exclusively to officers. Defence requirements stand on all fours with the civilian needs to which such forcible expression has been given in recent months.

In his James Forrest Lecture to the Institution of Civil Engineers on March 18, for example, Sir John Cockcroft suggested that a type of engineer should be trained who had a thorough grasp of the basic principles common to all engineering, and who was not just narrowly trained in the techniques of civil, mechanical, electrical or chemical engineering. "One of the greatest problems in the rapid build-up of atomic energy," said Sir John, "has been the shortage of engineers who can take charge of the design and building up of a complete project and who can, with their scientific colleagues, speed the development of really cheap power for nuclear energy. I am sure that this will apply to other fields of engineering in future." Again, Sir Hugh Beaver, pausing in his presidential address to the Institution of Chemical Engineers on April 30 to note how small a part of our administrators and legislators have had any scientific training, ascribed to this fact some of the difficulties in obtaining adequate support and encouragement for scientific education and research in Britain. Sir Hugh urged that more should be done to produce both the attitudes of mind and the conditions which would divert an adequate proportion of our financial resources and man-power into the use of research, and this is equally true of defence as in the civil field. The two are much too interlocked for any shortcomings in this respect in one field not to be felt in the other. For example, although the expenditure of the Ministry of Supply on research is to be cut by only £6 million to £217·4 million for the coming financial year, with a further £3·3 million off the cost of work at its research establishments, since the effort put into nuclear weapons and ballistic missiles is rising, the reduction in genuine fields of research may well be severe, even if research in nuclear weapons and ballistic missiles is not exceptionally expensive.

That of itself points to the soundness of some of President Eisenhower's proposals, and further support for them and especially for the view that the key problem is education is forthcoming from the Lees Knowles Lectures, "Cabinet Government and War", given by John Ehrman last year and recently published*. Mr. Ehrman's lectures follow naturally on Lord Hankey's lectures in 1945, "Government Control in War", and although he does not include in his survey the changes made during the stress of the Second World War, he brings into clear relief the essential administrative problems of defence which confront a democratic system of government such as that of Britain. Mr. Ehrman is concerned primarily with defence organization as an aspect of Cabinet government, although he does not limit himself to that aspect, and while he does not, like Lord Hankey, enunciate specific principles, Lord Hankey's principles are implicit in much that Mr. Ehrman writes. Indeed, unless final control remains in the hands of statesmen, working in the closest co-operation with the Service chiefs, with the Prime Minister of the day alone as head and the last word even in the grand strategy, Mr. Ehrman's lectures are of academic interest only.

Mr. Ehrman notes three main developments in the Cabinet system between 1940 and 1945. The Prime Minister's exceptional political authority enabled him to make exceptional use of his professional Service advisers, so that supreme control was exercised by a professional and not by a political committee, functioning under the ægis of the Heads of Government, while within the Cabinet system the Service Ministers disappeared from the inner counsels. Second was the creation of a powerful and extensive structure of civil committees of the Cabinet, comparable with that of the Committee of Imperial Defence, and this more effective and highly articulated hierarchy left its mark on post-war practice. Third, and in consequence, the War Cabinet itself was seldom used as an agent of administration even at the highest level, and Mr. Ehrman observes that Cabinet government, bearing its traditional responsibilities to Parliament, never functioned more effectively than during those years of war.

Throughout those years and the fifty preceding years, with which he is primarily concerned, Mr.

---

* Cabinet Government and War, 1890–1940. By John Ehrman. (The Lees Knowles Lectures, 1957.) Pp. xi+138. (Cambridge: At the University Press, 1958.) 16s. net.

Ehrman believes we can recognize a continuous process and that the central organization for defence has developed in an orderly way, thereby helping to preserve the essentials of Cabinet government and also those of the Parliamentary system within which Cabinet government operates—although with powers largely alien to a happier generation. It has been, he argues, one of the factors which has enabled Britain to adjust its economy and its political institutions, without violent interruption, to the burdens of total war. Mr. Ehrman emphasizes the debt which is owed to such men as Balfour, Haldane, Lloyd George and Churchill among Ministers, and to Sydenham Clarke, Hankey and Ismay among officials, but he does not minimize the importance of the system. That in turn had its effect on the men who used it, and the achievement which Mr. Ehrman stresses in these lectures is the re-incorporation of the higher elements in the Services, from their isolation in the nineteenth century, into the structure and habits of British administration.

This achievement, as he points out, was itself part of a more extensive and notable process, namely, the re-incorporation of one of the three classic activities of government, after a long period of virtual disuse, into the framework and traditions of government as a whole; and in that concluding sentence he displays the meaning of his study for all who are concerned not simply with the effectiveness of our organization for defence, but also with the relations between science and government upon which that effectiveness largely depends. The way in which the Services have been brought back within the orbit of the Cabinet holds lessons to be pondered by all who seek to improve the relations between science and technology and government, the administration of research and development, the balance of our scientific effort and the ways in which science and technology can make their full contribution to national welfare and defence. Outstanding among those lessons is the importance of the administrator and the expert, whether Service chief or scientist or technologist, being able to speak the same language; and we are once again reminded of the over-riding importance not merely of training the scientist or technologist so that he is competent to take wide views and assume high responsibility, but also the administrator and legislator, from statesmen downward, to be competent to appraise scientific and technical factors in a situation, to appreciate the significance of expert advice and to make judgments which take full account of the facts and are not warped by prejudice. While there is much in these lectures that suggests that the general form of President Eisenhower's proposals for the re-organization of defence in the United States is fundamentally sound and incorporates the lessons of British experience, it is on these latter lessons that they should direct fresh thought. To secure flexibility and understanding and receptivity demand, above all, attention to the educational issues as a matter of urgency and outstanding importance.

LEEUWENHOEK'S CORRESPONDENCE

The Collected Letters of Antoni van Leeuwenhoek
Vol. 5. Edited, illustrated and annotated by a Committee of Dutch scientists. Pp. xi+457+36 plates. (Amsterdam: Swets and Zeitlinger, Ltd., 1957.) 145*s*.

THE first four volumes of this exhaustive and beautiful edition of the works of Leeuwenhoek were reviewed in *Nature* in 1939 (144, 956), 1946 (157, 3), 1949 (163, 192) and 1953 (172, 696). The first five volumes of the twenty or so to be published have taken more than nineteen years to produce, and unless this rate can be speeded up very few of the present generation will still be living when the last volume appears. The present volume deals with only eight letters, of which numbers 86 and 87, 1685, have not been recovered, and are known only from brief extracts incorporated in later letters. They were concerned with the biology of the cochineal insect, at first wrongly interpreted by Leeuwenhoek, but on which he made some important observations in his later work.

The following letters, all written in 1685–86, are among those examined in this volume. In letter 82 (43) —figures in brackets are those of the earlier enumeration of the letters—crystals of a variety of liquids are described and figured, and it is noted that a gastrolith is absent in the crab, but present and obvious in the lobster. A bitch was dissected, and a quantity of material was found in the genitalia, but the spermatozoa are not mentioned in the letter, although they had already been seen and described by Leeuwenhoek in 1677 and 1679. In letter 83 (44), 1685, the obsolete term 'mishmash' appears in the English translation, although George Eliot uses it, and more recently, Lewis Carroll. In his work on crystals, in which he was greatly interested, Leeuwenhoek always used impure mixtures, which are hence often difficult and even impossible to identify, and in any event the resolving power of his microscopes was not sufficient for the purpose. The impregnated uterus of a bitch was dissected and he found in it "an enormous number of living animalcules" which he assumes are the "male seed" of the dog.

In letter 84 (45), 1685, the original seventeen figures have been lost, but six figures appear in all early printed versions except one, where there are only four. This is the famous letter on generation—a subject to which Leeuwenhoek devoted so much time and thought. The two parties in the controversy were the ovists, who maintained that the embryo was developed from an egg, as Harvey believed, and the animalculists, who held with Leeuwenhoek that the spermatozoon was a microscopic undeveloped fœtus complete in all its parts, although they were too small to be demonstrated by the microscopic equipment of the time. The ovists denied that the male seed ever reached the uterus, a belief denounced in the strongest terms by Leeuwenhoek as the most foolish and crude proposition accepted among physicians. Although Leeuwenhoek rarely expresses himself in language explosive and contemptuous, he admits that he is only an amateur anatomist, but is not dismayed that there are at least seventy authors opposed to his views on the spermatozoa. He compares the spermatozoon with the tadpole of Amphibia, but recognizes that the tail of the tadpole does not drop off, although that of the sperm does.

He attempts to determine the rate of movement of the latter, but is, of course, wrong in assuming that males and females can be distinguished. In this letter Leeuwenhoek describes also the complex structure of a sheep embryo seventeen days after the parents had mated. Having discovered all its essential parts, as he thought, he was induced to support the preformation doctrine of animal development. When Leeuwenhoek refers to shagreen "leather" the editors of the present work do not consider that he had in mind the *untanned* skin of certain cartilaginous fishes, but a product of the skin of mules and horses. It is perhaps more likely that he used the term as it was understood in England before his own time. Leeuwenhoek expresses great annoyance that his embryological observations are distorted and misunderstood, and have hence been falsely described in printed versions.

Letter 85 (46), 1685, is largely botanical and deals with the structure of a number of seeds, and how the embryo of the plant arises from them. He repeats that the spermatozoon is nothing but a miniature of the animal into which it will develop, but admits that he cannot assert this "with the slightest degree of certainty", and that therefore we must await the discovery of spermatozoa large enough to demonstrate their complex structure. He rejects spontaneous generation and claims that the only function of the female sex is to provide the male seed with the substances by which it is nourished and induced to grow. He discusses the nature of hybrids and the results of crossing different species. He holds that, as regards himself, it was becoming more and more irrefutable that an animal can arise only by the development of a spermatozoon in the uterus of the female, but how this is brought about he admits he cannot imagine.

Letter 88 (47), 1685, deals largely with chemical experiments on various liquids and solids (for example, gunpowder) and includes little new biological material. The origin of the chyle or milk vessels is briefly discussed, and the fibrous structure of the optic nerves of the ox and horse is assumed to carry a new substance from the brain to the eyes for their maintenance. The scales of fishes are covered by a slimy membrane the nature of which is investigated. This induced him to examine the scales of other fishes such as the eel, bream and perch, and finally the structure of the human skin. It is characteristic of Leeuwenhoek's work in general that it is by nature comparative—having discovered an interesting feature in one type he is always tempted to examine it in other related forms.

The last letter, of 95 pages, in the volume is number 89 (48), 1686, and is concerned entirely with chemical investigations into the nature of cinnabar, gunpowder, saltpetre and "crab's eyes" (gastroliths).

The present volume of this important series is completed by 95 pages comprising a list of contributors, a bibliography with biographies of authors quoted, indexes of names and subjects, a list of the figures and illustrations, and thirty-six plates.

The Leeuwenhoek Commission is to be warmly congratulated on maintaining the very high standard of book production which characterizes this series, notwithstanding the far higher cost of this volume. In one respect the present volume is superior to its predecessors in the improvement of the English translation, in which only the following slight blemishes were detected: p. 41, note 53, for 'gluery' read 'gluey'; p. 105, line 10, for 'consnsted' read 'consisted'; p. 141, note 3, 'tot' is not used for 'to' in modern English; p. 145, last line but one, for 'my' read 'me'; p. 149, note 13, read 'which'; p. 169, de Graaf's name wrongly spelt; p. 185, for 'unsearchable' read 'difficult'; p. 291, note 12, line 1, add 'neither' before 'head'.

F. J. COLE

ISAMBARD KINGDOM BRUNEL

Isambard Kingdom Brunel

A Biography. By L. T. C. Rolt. Pp. xii + 345 + 17 plates. (London and New York: Longmans, Green and Co., Ltd., 1957.) 25*s.* net.

THIS eminently attractive and readable book traces a career that abounds in both technical and dramatic interest. Mr. Rolt, as a trained engineer, writes with understanding of the technical problems which Brunel had to face. He is seen here at the age of twenty, as engineer-in-charge of the Thames tunnel workings, where he narrowly escaped death in a sudden inundation. There is the building of the Great Western Railway, the South Devon 'atmospheric' railway fiasco, and the construction of the great Saltash bridge. Mr. Rolt then turns to Brunel's steamship ventures: the P. S. *Great Western* and her pioneer crossing of the Atlantic under sustained steam power; the *Great Britain*, first iron-hulled and first screw-propelled Atlantic steamer; and, finally, the monstrous *Great Eastern*, an over-ambitious project, forty years in advance of its time.

That a man of such impact should have made enemies is almost inevitable. For example, Arthur J. Maginnis in his book "The Atlantic Ferry", published in 1892, wrote with reference to the *Great Eastern* that she "was eventually broken up at New Ferry, on the banks of the Mersey, almost in the same year (1890) that the *Great Britain* ended her career at the Falkland Islands, representing with the broad gauge on the railway, now also doomed, the last of the costly and bitter memories of the engineer Brunel, who, unfortunately for many, had more influence with great capitalists than other far more capable and less fanciful engineers".

After the turn of the century, however, the bitterness of such attacks had moderated; and in 1910 *The Engineer* said of him: "In all that constitutes an engineer in the highest, fullest and best sense, Brunel had no contemporary, no predecessor. If he has no successor, let it be remembered that . . . the conditions which call such men into being no longer have any existence".

Now in 1958, the centenary year, John Scott Russell's original model for the *Great Eastern* is still on exhibition to the public at the Science Museum in London, while his huge working model for the oscillating paddle engines, the largest of their kind ever constructed, revolves majestically in the background. In contemplating these authentic relics, one feels a certain grandeur rising above the sordid history of disappointment, failure and recrimination, which was directly responsible for Brunel's premature death.

In the preface to his book, Mr. Rolt mentions that he was at first inspired by curiosity as to Brunel's personality, rather than hero-worship; but one suspects that hero-worship must have come later. Mr. Rolt is an experienced writer, with a vivid and eloquent pen, and the reader may well be caught up in his enthusiasm. However, Mr. Rolt's is also a disciplined pen; he gives us a balanced and therefore convincing portrait of Brunel, as a man of exceptional talent and courage, the over-ambitious author of the broad-gauge railway and the premature giant steamship of the nineteenth century, a man whose outstanding achievements and failures alike bore the stamp of greatness.

H. P. SPRATT

COMPUTERS

Digital Computer Components and Circuits

By Dr. R. K. Richards. Pp. vii+511. (Princeton, N.J., D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1957.) 64*s*.

Digital Computer Programming

By D. D. McCracken. (General Electric Series.) Pp. viii+253. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1957.) 62*s*. net.

Mathematics and Computers

By George R. Stibitz and Prof. Jules A. Larrivee. Pp. viii+228. (London: McGraw-Hill Publishing Company, Ltd., 1957.) 37*s*. 6*d*.

THE above books, although all relating to digital computers, are very different in subject-matter and interest. "Digital Computer Components and Circuits" is a companion to a well-known book by the same author, entitled "Arithmetic Operations in Digital Computers", which deals with the logical design of the switching circuits used for various purposes in digital computers. The new book covers a much wider field, and the treatment is sufficiently detailed and comprehensive to make the book useful to engineers established in the field as well as to newcomers. It is notoriously difficult to write a good book on electronic circuits but the author has succeeded in doing so. He has brought together a great deal of design information otherwise only obtainable from scattered papers and has included much original discussion and comment. Subjects treated in the various chapters are as follows: switching circuits using diodes, vacuum tubes, transistors, and magnetic cores; magnetic and other forms of storage; circuits and tubes for decimal counting; analogue-digital conversion.

The second book is intended to provide a basic course in digital computer programming, and is of interest in that it is based on a hypothetical machine with an order code so chosen that all the basic techniques used in programming for any machine of the single-address type can be illustrated. The use of such an order code enables some of the stumbling blocks inherent in programming for a real machine to be avoided. No one, of course, can become a qualified programmer without experience in the practical running of problems, but the book is realistic in its approach, and should be useful to those who do not have access to a machine or who wish to make a preliminary study of programming before beginning work in earnest with a particular machine.

The third book, by Stibitz and Larrivee, is addressed to laymen. The authors set out "to present the computers as sober, unintelligent, but useful tools in the increasingly important applications of mathematics to science, technology, and business, and not as the weird and superhuman intelligence of science fiction, the popular press and, less forgivably, of some scientific writers who should know better". In this they have succeeded, although the technical level of the book is uneven, and in places the approach to the subject strikes one as being dated. The treatment of programming for modern digital computers is weak, and suggests that the authors have had little experience in this field. In the years just before and during the War, Dr. Stibitz was at the Bell Telephone Laboratories, and was a pioneer in the design of digital computers using telephone relays. Some sections of the book reflect his experience although, as is to be expected in a book intended for laymen, the information given does not add anything to what is obtainable elsewhere. Although the authors have, in general, been cautious about what they say, in their short section on language translation they may convey to some readers the idea that the use of digital computers in this field is more advanced than it actually is.

M. V. WILKES

FOUNDATIONS OF THERMODYNAMICS

Elements of Classical Thermodynamics for Advanced Students of Physics

By Dr. A. B. Pippard. Pp. vii+165. (Cambridge: At the University Press, 1957.) 25*s*. net. Clothbound; 15*s*. net. Paper covers.

THE first introduction of the fundamentals of thermodynamics to a student is necessarily of a brief and dogmatic nature and often he has attained no more than a facility for manipulating thermodynamic relations before he is diverted to other studies. Thus the re-examination of the fundamentals in the light of greater knowledge does not take place, and there is a growing need for this deficiency to be supplied. It is therefore a pleasure to welcome Dr. Pippard's book, which is concerned with the task of propagating a firm understanding of the bases of thermodynamics among students with a moderate acquaintance of the structure.

The first four chapters are devoted to establishing the zeroth, first and second laws of thermodynamics. While familiar enough in outline, the argument is very detailed, and every likely cause of confusion or ambiguity is carefully exposed and discussed. In most cases, the argument is presented in several different ways; thus reversible work is considered in detail not only in the standard case of a fluid under pressure, but also in the case of a body in a magnetic field; while the second law is developed both by consideration of Carnot cycles and of Carathéodory's law, the complementary nature of the two arguments being clearly brought out. The following chapters introduce the temperature scale, the thermodynamic functions and their derivatives, and their applications to simple systems. There follows a discussion of the thermodynamic inequalities in which the relations between entropy, availability, and energy functions are carefully explored and lead to the conditions for equilibrium. The consideration of phase equilibria in a simple substance follows, the last example, superconductivity, leading into the final chapter on high-order transitions, where order is introduced into this rather confused subject with a firm hand.

The book forms a nodal point, at which is drawn together the basic ideas the final-year student may be expected to know, their validity and limitations studied, and the way in which these ideas are used pointed out. At no time does the author content himself with dogmatic statement, and if an argument should lead too far from the main stream of this book the conclusion always gives the source in which the next stage of information can be found. Clarity is not sacrificed to brevity, and the writing flows smoothly from logical step to step.

There can be no hesitation in recommending this book to all undergraduates and postgraduates interested in thermodynamics, and many users of more advanced thermodynamics might well find pleasure in a study of this well-written account. The production of the book is of the usual standard of the Cambridge University Press, and, bearing in mind the preferred reader, it is good to see that an edition is available in paper covers at a substantial reduction in price. S. ANGUS

DISEASES OF BIRDS

Tratado de Doencas das Aves

Por J. Reis e P. Nóbrega, com a colaboração de A. S. Reis, R. C. Bueno e M. Giovannoni. Vol. 1: Pp. 391. Vol. 2: Pp. 416. Vol. 3: Pp. 318. Vol. 4: Pp. 428. 2a Edição, revista e ampliada. (São Paulo: Ed.ções Melhoramentos.) n.p.

TO undertake the compilation of a comprehensive work on a subject so enormous and ramifying as the diseases of birds requires courage. To complete such a work and present it in a manner that makes it of the greatest use, to both veterinary practitioners and students, is an achievement that does credit to the painstaking care and ability of the authors.

The "Treatise on the Diseases of Birds" by J. Reis and P. Nóbrega is now published in its second edition. The work was originally published in four volumes but in the new edition Vols. 1 and 2 and Vols. 3 and 4 are bound together to form two books only.

It is natural that the main bias of the work is toward the diseases of domestic poultry since it is in this field that the majority of work has been carried out, but information on matters of academic interest concerning wild birds is also included. The bibliography has been brought up to 1952 and, in some cases, more recent references are included. This fact alone will make the work useful even to those unable to read the Portuguese text.

The diseases are classified under their causative organisms. Thus, Part 1 is concerned with virus diseases, Part 2 with bacterial and fungal infections, Part 3 with diseases caused by Protozoa and parasitic arthropods and the last part deals with helminths and nutritional disorders. In Part 4, there are also sections on the pathological lesions of the organ systems, poisons, abnormalities of development, hygiene and a brief summary of surgical and general therapeutic measures.

In the parts dealing with virus and bacterial diseases the arrangement of the work is similar: the diseases are considered separately and a chapter is devoted to each. These chapters are in the nature of a complete account of the disease concerned. They begin with a synonymy of the common names of the disease in many languages, followed by a brief historical introduction and sections on geographical distribution, etiology, pathogenicity, symptoms, pathology, etc. At the end of each chapter is a bibliography of papers relevant to the disease under consideration.

The arrangement in Vols. 3 and 4 is slightly different in that the subject-matter is parasitological and each group of parasites is introduced by a brief general systematic account. The protozoan species recorded from birds are tabulated according to their hosts and are then discussed in groups with subsections dealing with the diseases in individual hosts. A somewhat similar arrangement has been used for the parasitic arthropods, but no keys for identification are given, and the whole group is dealt with from a systematic point of view, rather than by hosts. In the final volume the treatment of the various helminth groups is different. The nematodes are considered in groups according to the organs of the hosts in which they are found; the majority of the section on trematodes is devoted to lists of species found in both domestic and wild birds, again separated according to their site in the hosts; and the cestodes are dealt with in a similar manner except, of course, that position within the host is of little importance so far as the adult worms are concerned.

Vol. 4 closes with a general bibliography, eight coloured plates of pathological conditions and a comprehensive and most useful index.

It is realized that this account of the work does little to evaluate its merit in detail and, indeed, this would be a difficult task in view of the enormous field covered. The value of the inclusion of so much systematic detail in the helminthological sections is, perhaps, doubtful, since these groups are dealt with by many specialized works in a rather more satisfactory manner than is possible in this type of publication. In making this criticism I am undoubtedly biased by my own field of work.

In conclusion, it is perhaps best to summarize by suggesting that an English translation of the treatise would prove of great use to many people.

C. A. WRIGHT

ENTOMOLOGY IN REVIEW

Annual Review of Entomology

Vol. 3. Edited by Edward A. Steinhaus, in association with Ray F. Smith. Pp. vii+519. (Palo Alto, Calif.: Annual Reviews, Inc., 1958. Published in co-operation with the Entomological Society of America.) 7 dollars.

THE editors of scientific reviews have two main tasks; one is to ensure they get authoritative articles of current interest covering a wide range in the specialized field, and the other is to maintain a high scientific and literary standard in these articles. The reviewer of reviews may also consider these two aspects of policy and practice, and when the first two volumes of the "Annual Review of Entomology" were noticed in *Nature* (179, 1150; 1957) certain criticisms of the general policy were made, the main point being the disproportionately large number of articles devoted to the chemical control of insects. In the third volume, just issued, the balance is somewhat redressed, only 21 per cent of the space being devoted to insecticide work as against 35 per cent in both the preceding volumes.

The result is a book of better balance and much wider general appeal than hitherto, and it is clear from the preface of the work that the editorial committee is alive to its responsibilities in this respect. It points out, with justification, that the "Review" is not a one-volume work, the implication being that judgment should be suspended until a number of volumes are available. But if policy is still to a certain degree fluid it is now that constructive criticism would be most valuable.

One thing which is not yet clear is whether the editors want to make this review international, both from the point of view of contributors and consumers. That the one depends on the other to a certain extent cannot have escaped their notice, and yet in all three volumes more than 60 per cent of the contributors have been American. It is, no doubt, easier for the editors to maintain liaison with American authors and thus uphold the generally high standard of papers; but the dangers of excessive insularity appear not only in the choice of writers but also in their papers, several of which contain bibliographies which make it appear that their author is unaware that entomological research is also carried on outside the United States.

The useful practice of carrying articles on the same subject in successive volumes, by various authors of differing viewpoint, is again in evidence with the third article on the "Dynamics of Insect Populations", the current one being by A. J. Nicholson, who restates the evidence and replies to the criticisms in previous articles of the theory of density-dependent factors. Such a valuable series of papers underlines the advantage of a continuing, as against a one-volume, review. Insect physiology is well represented in the present volume by papers on the nervous system by K. D. Roeder, the uses of sounds in insects by H. and M. Frings, two papers on the nutritional requirements of insects by W. G. Friend and J. M. Legay, and perhaps above all by a short but most valuable paper by E. S. Hodgson on "Chemoreception in Arthropods" in which the author describes the new methods recently developed by himself and his colleagues, which have at last made it possible to determine in certain cases the responses of single chemoreceptors to a variety of stimulants. The essential unity and interdependence of all research are emphasized by the fact that this work has immediate relevance to at least four other papers in the same volume.

Papers on the chemical control of insects have a depressing tendency to turn into lists of neat little recipes for specific complaints, but the paper by R. E. Balch on "Control of Forest Insects" is an excellent antidote, giving as it does consideration to all the factors—not only chemical—relevant to insect control. Papers on biology and behaviour include two which reiterate the importance of background knowledge in control work: "The Feeding Habits of Biting Flies and their Significance in Classification", by J. A. Downes, and "Hybridization and Speciation in Mosquitoes", by L. E. Rozeboom. It is a little difficult to see the justification for including a paper on the "Biology of Scarabaeidae" (P. O. Richter), a subject so much narrower in scope than any other in the work.

The standard of the papers is high, the presentation good, and the index ample. Uniform bibliographies, in alphabetical order, might be considered as an improvement for the future. This volume is a definite advance on the previous ones in balance and appeal, and without doubt deserves to find a wide and appreciative public.

UNIVERSITY OF BOMBAY

A History of the University of Bombay, 1857-1957

By S. R. Dongerkery. Pp. vii+313. (Bombay: The University, 1957.) Rs. 15.

THE year 1857 was a sad year for the British administration in India, for the violence of the Sepoy Mutiny imposed a severe strain on Indo-British relationships. It is all the more remarkable, therefore, that at such a time there were men who pressed forward with measures to give form and substance to the concept of higher education in India by founding a university. Indeed, three universities, those of Calcutta, Bombay and Madras, were all founded within a few months of one another; later—on the occasion of the laying of the foundation stone of the University of Bombay in 1863—the Governor of the Province described these foundations as among the last, but not least, glorious deeds of the East India Company.

All the three universities were constituted on the model of the University of London, at that time a chartered body concerned only with examining and conferring degrees upon students trained in affiliated colleges. The defects of the affiliating system were realized later when London was reconstituted in 1900 as a teaching university after two Royal Commissions had reported in 1889 and 1894 respectively.

The corresponding activity in India culminated in the Indian Universities Act of 1904, but controversy there raged loud and long. A Committee on University Reform reporting in 1925 said that except in a loose and indirect sense, prior to 1912, the University of Bombay was not a teaching university, and since that date had only made a very partial approximation to the ideal. The Committee felt that it had been entrusted with the task of suggesting how that approximation could be made more complete.

Then came the Bombay University Act of 1928 which was a great advance and brought the work of the University into direct touch with the leaders of industry and the civic life of a large community. It focused the attention of the University on the conduct of postgraduate teaching and research as a direct responsibility and upon technology.

The reorganization of the Indian Union largely on a linguistic basis has resulted in the emergence of the University of Bombay (1953) as a city university, teaching in federal relationship with its constituent colleges and other recognized institutions. Unfortunately, the battle of the languages is not yet ended, and the future of the medium of instruction has still to be decided. The University has, however, been wise in adopting a cautious approach to this question.

The present volume, which is an extremely readable account of the growth of the University, also marks the centenary of its existence. It has had a chequered history, but it has been fortunate in commanding the devoted service over the years of men of eminence, erudition and foresight. On the whole, perhaps, things have turned out not as well as some hoped and not as bad as others feared.

The author, a versatile scholar intimately connected with the University administration for many years and as the Rector, was clearly well-placed to write this book, and he has provided a pleasing volume giving a fair and full picture of the development of the University and of the dedicated men, both British and Indian, who have shaped its course.

L. A. JORDAN

A School Course of Biology

With Suggestions for Experimental and Field Work. By L. J. F. Brimble. Fourth edition, entirely re-written and enlarged in collaboration with Dr. L. M. J. Kramer. Pp. xv+558. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1957.) 18*s*. net.

THE transformation of a school text-book, which has been in steady demand since 1940, into what is virtually a new volume should endow it with a fresh lease of useful life. It is not a cram manual streamlined to fit the requirements of some examination syllabus: instead, it sets out bravely to present a representative picture of all forms of living matter as they exist now and have originated in the past, and to describe their structure, functions, organization and inter-relationships, including those with man himself.

The chapters on evolution and heredity, living things and their environment, and man in relation to other living organisms are particularly welcome. In these respects the book merits comparison with the attractive readers put out for use in American high schools; and one hopes that some copies will find their way across the Atlantic. For British teaching practice it covers the ground for the General Certificate of Education (Ordinary Level), in many directions extending far beyond it, for it contains a large amount of miscellaneous information on such topics as the speed of animals, the life-history of the eel, parasitic and saprophytic plants.

The treatment is comparative. Directions given at the end of each chapter for individual and class observations and experiments are more than adequate. Among the many well-chosen illustrations, the drawings by the senior author deserve special commendation for their number, clarity and artistic form. The book contains one or two slips in phrasing, and a few minor errors of fact, which merely serve to show that it is impossible for a single author to be fully informed on every topic receiving mention. By the same token, the boys and girls who will study it should not be expected to remember all the knowledge it contains. R. WEATHERALL

Analytical Microscopy

Its Aims and Methods in Relation to Foods, Water, Spices and Drugs. By Dr. T. E. Wallis. Second edition. Pp. viii+215. (London: J. and A. Churchill, Ltd., 1957.) 25*s*. net.

REVISED for the first time since its publication more than thirty years ago, this book is virtually new, owing to the accumulation of fresh information and the introduction of new methods.

An account is given of the methods of preparing material for microscopical examination and is illustrated by examples selected almost entirely from problems which have arisen during the career of the author. Analytical microscopy, its aims and methods in relation to food, water, spices and drugs, clearly indicates the unequalled experience of an analyst known to many in industry and medicine.

The immensely practical nature of this work is shown by the varied use of the microscope for solving problems which cannot be successfully tackled by purely chemical means.

The introductory chapter deals with general arrangements for the proper use of the microscope and its accessories, followed by a chapter giving details of preliminary operations which are necessary for the examination of foreign matter (including insects) in poultry and bird food. The use of surface preparations is described with reference to the microscopical characters of culinary herbs, and the method of sedimentation is illustrated by investigations of water deposits. The process of kneading is explained in connexion with the analysis of flour and other starchy powders, while other chapters deal with elutriation for preserves and the reagents used for the clarification of specimens. Additional preliminary treatment of material is described by some information on 'crude fibre' in connexion with coffee and chicory. Chemical treatments used prior to the examination of pests, occurring as fragments in flour and other commodities, are mentioned. Chemomicroscopy, the micromorphology of various substances including sulphur, the techniques of sublimation and precipitation—all indicate the extensive scope of this handy volume.

For those wishing to use microscopical measurements, numerical values and quantitative microscopy, the author gives a concise account of the meticulous approach to these subjects. Accurate, well-labelled drawings are a great feature of this book, while valuable numerical data, reagent formulæ and an adequate bibliography complete the store of information available to anyone engaged in analytical work using the microscope. S. B. CHALLEN

The Amphibia of Ceylon

By P. Kirtisinghe. Pp. xiii+112+1 plate. (Colombo: P. Kirtisinghe, 2 Charles Circus, 1957.) n.p.

THE Ceylonese Amphibia are presented here in the form of a taxonomic survey, the general subjects of habits, life-history and ecology being almost completely disregarded. This is a disappointing omission in a book with as definitive a title as "The Amphibia of Ceylon" and in one which would have provided scope for speculative treatment of zoogeography, speciation and other aspects of amphibiology. None of these subjects has been given the attention that is required, perhaps because no research in these fields has been attempted by the author. Instead, Mr. Kirtisinghe has restricted himself to a taxonomic treatment. However, it is a compact and nicely produced book and makes a very useful manual for the museum laboratory worker as well as a reliable field book for the collector.

Preceding the main taxonomic section is a historical account of the study of Ceylonese Amphibia in which the author has collated the faunal lists which have been published by earlier devotees to Ceylon's amphibians. In the light of Mr. Kirtisinghe's experience, which has accrued from his position as lecturer in zoology at the University of Ceylon, from his personal collections and from the year spent in England when he devoted a great deal of time to the study of the Ceylon amphibians in the British Museum collections, he concludes that the composition of Ceylon's amphibians can be reduced from the 37 species recognized by Boulenger to 32, with 12 species believed to be endemic. Although his reasons for synonymizing these and other species may be based on sound judgment, they are not always divulged and the reader is kept guessing.

The same style is adhered to throughout the systematic section—division into families with keys to the genera and species, and within each species account there is, first, a synonymy, followed by a figure and detailed description of the adult, and of the larva also where it is known, and range. The illustrations are well executed by competent artists.

A. G. C. GRANDISON

SOME EFFECTS OF THE FINE STRUCTURE OF THE IONOSPHERE ON TRANSMISSIONS RECEIVED FROM THE RUSSIAN EARTH SATELLITE 1958δ

By F. A. KITCHEN and W. R. R. JOY

Royal Naval Scientific Service

A SERIES of simultaneous direction-finding and Doppler frequency-shift measurements has been made on the radio transmissions from the Russian satellite 1958δ, on a frequency of 20·005 Mc./s., with the initial object of determining the parameters of local tracks, and hence those of the orbit. As previously discussed[1], these techniques enable the following parameters to be derived, in principle, from observations made during one local transit: velocity, plan and slant ranges (hence the height of the satellite), and bearing of the sub-satellite point at the instant of closest approach (hence track-heading of the satellite at this point). During the course of precise observations on 1958δ, however, some interesting anomalies were observed in the Doppler measurements. These confirmed the existence of similar effects previously noted in the case of observations on 1957α and 1957β, when less-accurate measuring techniques were available. In the system at present in use, all information on bearing, Doppler frequency and time is recorded synchronously on separate channels of a multi-channel tape recorder. An Essen ring quartz-crystal oscillator operating at 100 kc./s. with a frequency drift of less than + 2 parts in 10^{10} per day was used to provide the time reference throughout the system. It was also used to drive a precise frequency synthesizer to generate a local reference signal for comparison with the signal received from the satellite, at radio-frequency. Errors in the frequency measurements originating within the receivers were thus eliminated. Some samples of track parameters deduced for 1958δ are given in Table 1.

Table 1. LOCAL TRACK PARAMETERS DEDUCED FOR 1958δ, ASSUMING A FLAT EARTH AND REFERRED TO PORTSDOWN (lat. 01° 06′ 53″ W., long. 50° 51′ 30″ N.)

Date	Revolution No.	Velocity (km./sec.)	Min. plan-range (km.)	Min. slant-range (km.)	Height (km.)	Track heading at closest approach (deg. true)	Inclination of orbit to equator (deg.)
16.5.58	17	8·16	15·8	258	257	040	62
20.5.58	71	8·11	129	318	291	043	64
21.5.58	85	8·12	722	766	290	043	65
22.5.58	98	8·12	230	370	290	040	65

The average period of the orbit between revolutions Nos. 71–98 was 105 min. 53·8 ± 0·1 sec.

One of the anomalies detected in the Doppler observations is a time displacement of the apparent instant of closest approach of the satellite, relative to that deduced from direction-finder observations. Evidence of the reality of this time difference was obtained during revolution No. 71 from south-west to north-east, on May 20, when the normal direction-finding and Doppler frequency-shift observations were supplemented by direction-finding measurements at a remote station about 300 km. distant. Observations from this latter station were recorded synchronously with the results being obtained locally, on the multichannel recording equipment. The times of closest approach to the two stations derived from the simultaneous direction-finding measurements were mutually consistent, and in agreement with the known parameters of the track involved, whereas the corresponding instant deduced from the Doppler observations at Portsdown was 6 sec. earlier than indicated by the associated direction-finder results. This is shown in the graphical transcription reproduced in Fig. 1. The time discrepancy is much greater than would be expected from the inclination of the track relative to the surface of the Earth, particularly since the local track is very near perigee. The phenomenon is considered to be due to the influence of the ionosphere, and it may be explained by refraction of the radiation from the satellite transmitter through part of the *F*-region having a tilted lower boundary, of the type reported by Bramley and Ross[2].

It has been shown[3,4] that refraction of satellite transmissions by the ionosphere will result in a virtual source displaced from the actual source, the displacement increasing with increasing range. In addition to the influence on Doppler records, the effect of this

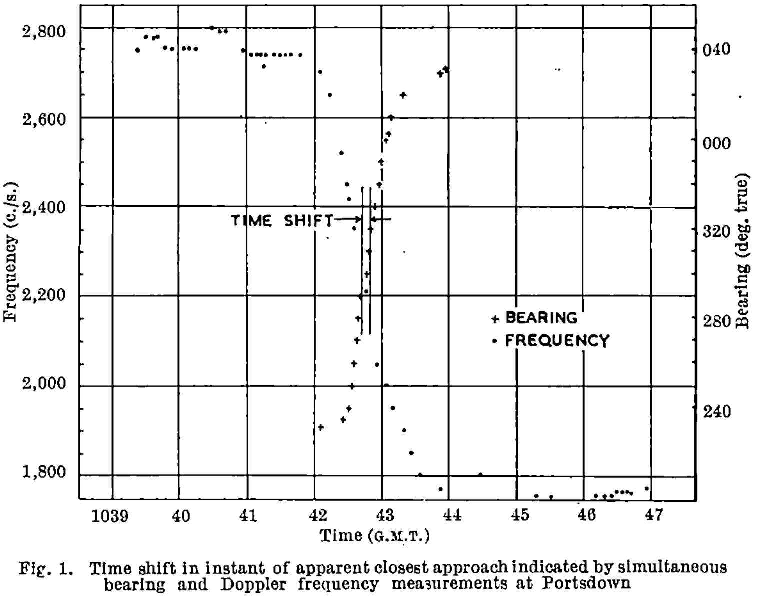

Fig. 1. Time shift in instant of apparent closest approach indicated by simultaneous bearing and Doppler frequency measurements at Portsdown

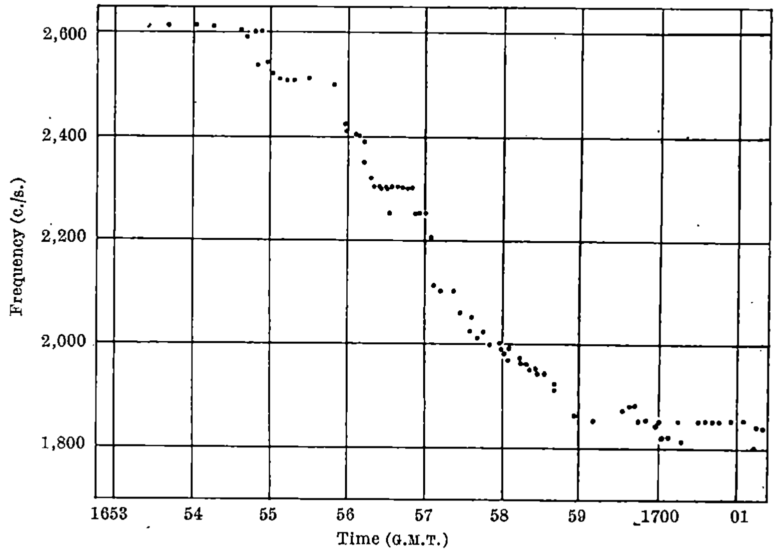

Fig. 3. Examples of discontinuities in a Doppler frequency record

refraction would also be expected to give rise to associated changes in direction-finding, but the resulting errors will be small in the case of local tracks. In the case where the ionosphere is concentric with the surface of the Earth, the refraction would result in an error in estimation of slant-range from the Doppler measurements, but not in the time of closest approach.

Fig. 2 is a simplified illustration to show how a tilted lower boundary on the $F2$-region of the ionosphere produces the time shift in the instant of closest approach deduced from the Doppler observations. The diagram depicts the case of a satellite moving above a tilted lower boundary of an ionosphere of constant refractive index on a track concentric with the Earth's surface, and over the observing point. The virtual sources are shown, as for example, 2′ corresponding to the true position 2. Again, the effects on Doppler frequency will be expected to be more marked than the corresponding effect on direction-finding observations. In the practical case where the point of observation does not lie in the sub-satellite path, the effects due to refraction will be correspondingly increased.

It is thus expected that refraction by the ionosphere will cause significant errors in the estimation of slant-range and hence height of satellite. Further, that tilts in the lower boundary of the ionosphere will increase these errors, and simultaneously introduce a shift in time of apparent closest approach of several seconds, in a sense depending on the orientation of the lower boundary at that time.

Occasionally time differences of as much as 20 sec. have been measured, in which time the satellite travels a distance comparable to the height and range. It appears unlikely that such large time-shifts are due entirely to ionospheric tilts.

Referring to Table 1, it will be seen that there is a spread in the apparent heights of 1958δ. However, for revolution $N = 17$, when the satellite passed nearly over the observing point, the ionospheric effects were minimized, and the deduced height shows nearer agreement with that obtained by the Royal Aircraft Establishment[5] using an interferometer at 40 Mc./s. The greater apparent heights quoted for subsequent revolutions are due to variations in the refractive effects described.

Fig. 2. Effects of refraction in an ionosphere with tilted lower boundary (schematic, not to scale)

Fig. 3 illustrates the marked discontinuities in the Doppler frequency which occur at irregular intervals. This is a typical phenomenon for most of the observations on 1958δ, whether the satellite was approaching or receding from the apex, but was more pronounced in the latter case when the satellite was at greater heights. The magnitudes of the discontinuities in the frequency record are usually too great to be accounted for by alternate reception of ordinary and extra-wave magneto–ionic components of the transmission. It appears more likely that the discontinuities arise from the existence[6] of smaller-scale irregularities in the tilted lower boundary of the F-region, the whole of which is in effective random motion. Similar effects were not observed in the direction-finding bearing records.

It is of interest to note that if the Doppler readings are made sufficiently accurately, and at frequent enough intervals, then in many cases the irregularities observed make it impossible to process the results in the manner described by Hampton[7].

Arising from this work, it appears practicable to make a detailed study of the fine structure of the lower boundary of the F-region of the ionosphere, by analysis of the detailed character of the Doppler frequency discontinuities in conjunction with accurately known orbit parameters. Attention is now being given to this aspect of ionospheric research. The fact that wide variations of direction-finding observations have not occurred in this work leads to the assumption that the influence of sporadic E-ionization has been insignificant.

Other effects of the ionosphere on the Doppler frequency-shift recordings arise due to : (a) a change in the electrical length of the path from the satellite to the receiver ; (b) in general, a change in the velocity of propagation of the radio signals in the vicinity of the satellite.

The contributions these phenomena would be expected to make to the observed Doppler frequency-shift have been estimated, and found to be small. For example, if the satellite is above the maximum of the $F2$-region ionization, the effect of (a) is to increase the apparent height by about 9 km. for an assumed total electron content of 10^{13} per cm. column. When the satellite is in the vicinity of the $F2$-region maximum, the effect of (*b*) is merely to change the received frequency by not more than a few cycles per sec.

This communication is published by permission of the Admiralty.

EFFECT OF AIR DRAG ON THE ORBIT OF THE RUSSIAN EARTH SATELLITE 1957β: COMPARISON OF THEORY AND OBSERVATION

By D. G. KING-HELE and Dr. D. C. M. LESLIE
Royal Aircraft Establishment, Farnborough

IF the orbit of an Earth satellite has an eccentricity greater than about 0·02, most of the air drag is encountered near perigee. Consequently, there is a retardation near perigee and a reduction in height at the next apogee, but very little decrease in perigee height. Thus the orbit contracts and becomes more nearly circular, while the orbital period decreases because the major axis is diminishing.

The equations of motion can be solved analytically if certain simplifying assumptions are made, and the most useful solutions appear to be those obtained under the following assumptions: (1) The Earth and the atmosphere are spherically symmetrical; (2) the density ρ of the atmosphere at a given height is constant from day to day; (3) ρ varies exponentially with distance from the Earth's centre r: ρ is proportional to $\exp(-r/H)$, where H, the 'scale height', is assumed constant; (4) the aerodynamic force acting on the satellite is taken as $\rho v^2 S$ tangential to the path, where v is its velocity and S is a constant which may be interpreted as the effective cross-sectional area of the satellite; (5) the eccentricity e of the orbit is small, so that high powers of e may be ignored; (6) the presence of air drag changes the orbit during any one revolution by only a small amount, the square of which can be neglected.

Under these assumptions, the relevant orbital elements can best be written in the forms given below. If the eccentricity e is sufficiently small for terms of $0(e^2)$ to be neglected, the orbital period T can be expressed as a function of time t in the form:

$$\frac{T}{T_0} = 1 - \frac{3H}{2a_0}\left\{\ln I_1\left(\frac{a_0 e_0}{H}\right) - \ln\sqrt{1-\frac{t}{t_L}}\, I_1\left(\frac{a_0 e_0}{H}\sqrt{1-\frac{t}{t_L}}\right)\right\} + 0(e_0^2) \qquad (1)$$

where a is the semi-major axis, suffix 0 refers to initial conditions, and I_1 is the Bessel function of the first kind of imaginary argument and order one. t_L may, for brevity, be called the life-time, though it is slightly greater than the true life-time, because it gives the time at which T drops not to the lowest practical value (say, 87 min.) but to minus infinity. For *Sputnik* 2, t_L was about 0·6 per cent greater than the true life-time.

Equation 1 has the virtue that it is valid up to the last revolution of the satellite, but for most practical purposes it is preferable to have a formula which includes terms of $0(e^2)$ and avoids Bessel functions. The appropriate form is:

$$\frac{T}{T_0} = 1 - \frac{3}{2}e_0\left(1-\frac{5}{3}e_0\right)\left(1-\sqrt{1-\frac{t}{t_L}}\right) - \frac{17}{8}e_0^2\frac{t}{t_L} + 0(e_0^3) + \frac{3H}{8a_0}\ln\left(1-\frac{t}{t_L}\right) + 0\left(\frac{H^2}{a^2}\right) \qquad (2)$$

The growth of error in (2) as t approaches t_L declares itself plainly, for the term in H/a_0 becomes large, so that the $0(H^2/a^2)$ term can no longer be neglected. By differentiating (2), t_L can be expressed as:

$$t_L = \frac{3}{4}\frac{e_0 T_0}{(-\mathrm{d}T/\mathrm{d}t)_0} \times \left\{1 + \frac{7}{6}e_0 + 0(e_0^2) + \frac{H}{2a_0 e_0} + 0\left(\frac{H^2}{a_0^2 e_0^2}\right)\right\} \qquad (3)$$

When e_0 is very small, say less than 0·02, equation 3 becomes inaccurate, and the appropriate form is that obtained from (1):

$$t_L = \frac{3}{4}\frac{e_0 T_0}{(-\mathrm{d}T/\mathrm{d}t)_0}\frac{I_0(a_0 e_0/H)}{I_1(a_0 e_0/H)} \qquad (4)$$

where I_0 is the Bessel function of the first kind of imaginary argument and order zero. Leslie[1] gave a limiting form of (4), under the assumption that $a_0 e_0/H$ was not too small; Groves[2] derived a version of (3); and Parkyn[3] gave (2) without the $0(e^2)$ terms.

The distance of perigee from the Earth's centre, r_p, is given by:

$$r_p = r_{p_0} + k_0 - k + H\ln\frac{k\, I_1(k/H)}{k_0\, I_1(k_0/H)} + 0\left(\frac{H^2}{r_p}\right) \qquad (5)$$

where $k = er_p/(1+e)$. If e is greater than 0·01, equation 5 can be expressed as:

$$r_p = \left\{r_{p_0} - \frac{H}{2}\ln\frac{e_0(1+e)}{e(1+e_0)}\right\} \times \left\{1 + 0(e_0^3) + 0\left(\frac{H^2}{a^2}\right)\right\} \qquad (6)$$

from which it follows that the relation between T and e is of the form:

$$\frac{T}{T_0} = \left(\frac{1-e_0}{1-e}\right)^{3/2}\left\{1 - \frac{3H}{4a_0}\ln\frac{(1+e)\,e_0}{(1+e_0)\,e} + 0\left(\frac{H^2}{a^2}\right) + 0\left(\frac{H}{a}e\right)\right\} \qquad (7)$$

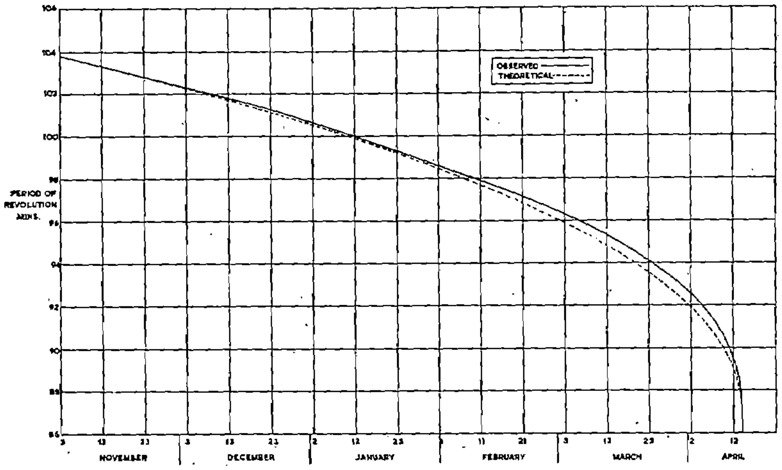

Fig. 1. Period of revolution of *Sputnik* 2 between November 1957 and April 1958. (*Crown copyright reserved*)

Once the initial values e_0 and T_0 are known, equation 7 should provide a good indirect method of finding e. The variation of eccentricity with time is given by:

$$\frac{e}{e_0} = \sqrt{1 - \frac{t}{t_L}}\left[1 - \frac{e_0}{6}\left(1 - \sqrt{1 - \frac{t}{t_L}}\right) + 0(e_0{}^2) + 0\left\{\frac{H}{a}\ln\left(1 - \frac{t}{t_L}\right)\right\}\right. \qquad (8)$$

Equation 8 shows that the variation of e^2 with time is nearly linear, so long as the terms in e_0 and H/a_0 remain small.

The observational values of T and dT/dt for *Sputnik* 2, which are given in Figs. 1 and 2, are based on the analysis of some four hundred observations received at the Royal Aircraft Establishment in the course of the prediction service which was provided from January until April 1958. Most of the observations were accurate to ± 1° in direction and ± 2 sec. in time, though some were much more accurate. Each observation was used to estimate the time at which the satellite passed through apex, the point of maximum latitude north, and the root-mean-square error in determining apex time was usually not more than about 3 sec. From two apex times approximately a day apart, the mean nodal period of revolution T in the interval could be determined with root-mean-square error usually not more than 0·3 sec., or 1 part in 20,000. The series of values of T was then differenced, at intervals Δt, to give values of $\Delta T/\Delta t$ for comparison with the theoretical dT/dt. The value of $\Delta T/\Delta t$ could be obtained with a root-mean-square error usually not more than $0{\cdot}4/\Delta t$ sec./day, where Δt is in days. Except in the last four days of the life of the satellite, a lower limit of 0·8 day was set for Δt, to avoid large errors. Sometimes, through lack of observations, Δt had to be taken as high as 10 days. It would be possible to produce an improved version of Fig. 2 by determining the apex times more accurately and by a proper

Angle from apex to perigee	− 31°	− 55°	− 76°	− 91°	− 98°	± 1°

Initial inclination of orbital plane to equator, 65·3°. Last column gives root-mean-square errors.

statistical treatment of the results, to decide, for example, the optimum value of Δt. However, the labour required scarcely seems worth while, when independent results from other countries will no doubt soon be available and will show whether there are any spurious values in Fig. 2.

The theoretical curve drawn for comparison in Fig. 1 is that obtained from equation 1, with November 4·0 as initial point, $t_L = 162 \cdot 0$ days and $H = 30$ nautical miles. The agreement between observation and theory is fairly good. But it is by no means perfect, and this is scarcely surprising in view of the irregularities in Fig. 2.

There are two contrasting features of interest in Fig. 2. First, it appears that the theoretical curve provides a reasonable mean value of dT/dt, suggesting that the effective cross-sectional area S underwent no great and irreversible change. This conclusion is consistent with observation, for until April 12 the brightness of the satellite fluctuated widely when it was between the observer and the Sun, and the period of these fluctuations was usually between 1½ and 2 min. These regular changes suggest that, until April 12, the satellite may have been rotating at a roughly constant rate, and that the mode of rotation, for example, a tumble or a barrel roll, may have remained the same. If so, the mean effective area S would be expected to remain constant. The second interesting feature of Fig. 2 is that the observed values depart significantly from the theoretical. Anyone who tried to predict the transits of the satellite will confirm that these oscillations in dT/dt are real, and not due to errors of observation or analysis. Taking theory instead of observation for January 20–February 9, for example, would have led to an error of about ½ hr. in the predicted times. It seems probable that the fluctuations in dT/dt are caused by day-to-day fluctuations in the properties of the atmosphere at perigee, either by changes in the number of particles per unit volume or in their electrical state. Though there is no obvious pattern in the fluctuations of Fig. 2, an oscillation of period about 25 days is faintly discernible, and this has provoked speculation that the tide-raising force of the Moon may play some part. There are many other possible sources for the irregularities, however, and it would be premature to attempt any detailed discussion of them here.

The value of H, the scale height, can in principle be obtained from the orbital data of Table 1, by means of equation 6 or equation 7; but since H depends on the small difference between two large quantities, considerable errors are inevitable. If the initial values are taken as those in the first column of Table 1, and H is determined from (7), using each of the other four columns in turn and giving each equal weight, the value obtained for H is 38 ± 13 nautical miles, almost all the error arising from the error of 0·0006 in e. The errors can be minimized by taking only the last of the four columns. It is then found that $H = 35 \pm 4$ nautical miles from either (6) or (7). Though the error is smaller, the result should still be received sceptically, for several reasons. First, because of the Earth's oblateness the value of H obtained is not the scale height as customarily defined, relative to height above the Earth's surface; when oblateness is taken into account, H is increased by about 25 per cent. Secondly, the irregularities in dT/dt violate one of the assumptions of the theory. Thirdly, H varies with both latitude and height, thus violating two more assumptions. Fourthly, electrical effects may be important and, if so, ρ is not the true air density. For these reasons it is obvious that much further study is required before a reliable value of H can be derived.

We wish to thank the many independent observers who provided the observations for Figs. 1 and 2, and Miss D. M. C. Gilmore, who analysed the observations and prepared the graphs.

THE BIOGEOGRAPHY OF AUSTRALIA

By PROF. RONALD GOOD

University of Hull

IT has been suggested[1,2] that the biogeographical problems of Australia become less perplexing if it is assumed that Australia and New Guinea, instead of being parts of one and the same primeval land mass, have attained their present proximity in comparatively recent geological times, by some relative movement which has gradually diminished the distance between them. Such a diminution might be caused by an active drift of Australia in an easterly or northerly direction; or to an active drift of the Melanesian–New Zealand arc westwards; or to some combination of these; but at present it is simplest to speak of the drift of Australia towards New Guinea, remembering, nevertheless, that this may be only a relative description.

A theory of this kind must depend largely on circumstantial evidence and the field in which this may be sought is wide, since there is scarcely a cognate science which cannot contribute to it. It seems justifiable, therefore, in order to indicate where this is likely to be most valuable, to suggest in rather more detail, and particularly in botanical terms, one course which events may have taken.

To begin with, plant geographers have long remarked the considerable affinity between the floras of Australia and South Africa, an affinity typified most familiarly by the families Proteaceae and Restionaceae, and by the Ericales, but seen also in many other plant groups. There seems no doubt that this is a true genealogical affinity, and we may therefore postulate that at some earlier period Australia, as we now call it, was much closer to (perhaps actually in contact with) what we now call South Africa, and therefore that its relative movement has been, in general, eastwards.

When, accepting this premiss, we consider the possible direction of movement more closely, an important point at once emerges. If we assume that the drift was directly eastward, then Australia would have remained within the same range of latitude throughout its journey ; but if, on the other hand, the drift was to some degree north-eastward, then Australia would, in the course of it, gradually have altered its position in respect of the poles, which for the moment we may regard as retaining their positions. The difference between the two from the botanical point of view is great. In the first case we should expect the original flora of Australia to continue unembarrassed by serious climatic change and to alter no more than might be expected from the prolonged passage of time alone. In the second case, the flora would be under continued and increasing stress through the gradual movement from one climatic condition to another.

In other words, Australia, unless it maintained a true latitudinal course, is likely to have moved so that it came to fall more and more within the warmer and drier conditions of the southern high-pressure belt or horse latitudes, and less and less within the cooler and wetter conditions of the south-temperate low-pressure belt of the roaring forties and north-westerlies. If this movement was considerable, then Australia would even have moved entirely out of one major climatic zone into another.

To-day there are in the Australian flora, in addition to what we may call the basic 'Afro-Australian' element already mentioned, two other great floristic elements, the 'south circumpolar' rain-forest element found now in south-east Australia and particularly in Tasmania (as well as in New Zealand and South America), and the 'Melanesian' rain-forest element of eastern Queensland and north-eastern New South Wales. The presence of the former (of which there is no counterpart in the present South African flora) suggests strongly that Australia was at one time in continuity with a general southern-temperate rain-forest flora and, thus, that its original position was somewhat to the south of Africa and, perhaps, even between that continent and what is now Antarctica. In this position we should expect its flora to consist of two main elements—one in the north having much in common with the nearby South African flora, and a temperate circumpolar element in the south.

From this position we may picture Australia as having drifted at least east-north-east, and it may be almost north-east, and the change in latitude involved as amounting to as much as 20°. Such a move would be likely to cause great floristic changes. In an original position of, let us say, 30° to 60° S., Australia would have lain with only its most northerly portion in a comparatively dry zone and with most of its area in a cooler and much wetter zone. In its present position between 10° and 40° S. it is almost wholly in a dry zone, and only some of its more southerly parts have a wetter and cooler climate. There are, indeed, only two, adjacent, parts of the continent in which rain-forest occurs to-day, namely, the south-east corner with Tasmania, where there is a circumpolar type, and along the warmer east coast, where here and there a more Melanesian type of rain-forest occurs.

Now let us view this supposed drift of Australia from another aspect. At first the movement would have been mainly one of gradual separation from its neighbours, but this would soon amount to a considerable measure of isolation. Moreover, if the relative positions of the other land masses were, and remained, as we know them to-day, then this isolation would not only increase but also would persist for most of the journey, diminishing again only in the later stages as Melanesia was approached. Hence, for much of the time, which may have been a very long period, not only would Australia have been isolated from other lands but also it would have been moving gradually from one climatic zone to another.

In such circumstances it would seem almost inevitable that the flora must have been affected profoundly. On one hand the major area of temperate rain-forest would have become more and more restricted to the south, and on the other, increasingly wide aridity would probably have greatly changed the distribution of the Afro-Australian element. Most important of all, the isolation of Australia from other land masses would have hindered any replenishment of the flora from elsewhere. We should therefore expect that as drift continued the general character of the flora of Australia gradually became changed and probably more drought-resistant, in any event over much of the continent. It may be highly relevant in this connexion that despite the assumption of close prior association with southern Africa, Australia has, unlike South Africa, practically no specialized desert flora to-day, although its arid areas are now at least as extensive. This suggests that at its time of separation from Africa it lacked either the stock from which the African desert flora has or had come, or the appropriate climatic conditions.

Because of these circumstances, a most interesting situation would have arisen as Australia gradually came within population distance of Melanesia. In the first place, it would have arrived in a floristically unsaturated condition ready to be replenished easily at the first opportunity. In the second place, it would have reached a point geographically at which certain local parts of it on the east would have been particularly capable of sustaining tropical rain-forest but of which there would have been no available sources in Australia. It would therefore not be surprising if there was a very rich and rapid invasion of plants from Melanesia as soon as diminishing distance permitted, not only, though perhaps primarily, in the form of rain-forest down the east coast, but also more generally in the form of potentially more drought-resistant elements. Australia may indeed have afforded something like a partial floristic vacuum into which plants from Melanesia would have flowed quickly and easily.

If this was indeed the course of events, we should expect to find, in the present Australian flora, certain prominent features. We should expect to find some remnant of the old temperate rain-forest flora which once covered most of the continent, because the south-east is still as far from the equator as 40° S., and this we see plainly in the flora of much of Tasmania and parts of the adjacent mainland.

We should expect to find in the remaining less-arid parts the general occurrence of the old Afro-Australian flora, and this we do very conspicuously, for it still provides much of the most typical Australian plant life. We should expect a relative absence of specialized desert types because the conditions for their development came after the separation of Australia from areas with such types now, and this, of course, is true. Finally, we should expect to find a strong infiltration of Melanesian types, mostly tropical rain-forest plants, in the north and east wherever the rainfall is sufficient, and the presence of this kind of vegetation in the high rainfall areas of the north-east is familiar and conspicuous.

Hence the sequence of events outlined provides a reasonable explanation of the major features of the present Australian flora without recourse to former land connexions of any kind, except in so far, of course, as the present Torres Straits have almost certainly been dry land on occasion during the very recent geological past, that is to say, on the present hypothesis, since Australia reached New Guinea.

It will be clear now that two very important aspects of the circumstantial evidence mentioned earlier will be the palæontological and the palæoclimatic, and it may therefore be reiterated that according to my hypothesis I should expect the Angiosperm fossil record of much of Australia to show in sequence, first a fairly widespread flora predominantly of a temperate rain-forest kind; secondly, a contraction of this and a spread of an 'Afro-Australian' flora (such as is exemplified by acacias, Proteaceae, Restionaceae, Ericales and various Monocotyledons); thirdly, more widespread evidence of aridity accompanied or closely followed by a great increase in such plants as *Casuarina* and *Eucalyptus*, together with the appearance of some development of tropical rain-forest in the north-east and east; and fourthly, one or more short-term extensions of the more mesophytic kinds of vegetation during the pluvial stages of the Pleistocene.

There is not yet much to guide us in dating these successive phases, but there are one or two pointers. In the larger plant groups, particularly families, there is, with one particular exception to be mentioned, good agreement between the present floras of South Africa and Australia, and it seems clear from this that if the two regions have indeed drifted apart then the process must have begun after the general differentiation of the Angiosperms, that is to say, not earlier than the later Cretaceous or the earliest Tertiary. On the other hand, it may, so far as the plants are concerned, have started at almost any later time, the more recent the start the shorter, of course, being the duration of the movement. Again, whether drift has been going on slowly for a long time or has taken place wholly within a comparatively short time, we do not know. At the nearer end of the time-scale the considerable size of the Melanesian element in the Australian flora to-day (together with the much smaller selection of Australian plants in New Guinea) suggests that an appreciable time has elapsed since these two became close enough together to populate one another, and this in turn may merit the speculation that their approximation was during or at the end of the Pliocene.

On one point the fossil record may be of special importance. The underlying affinity of the floras of South Africa and Australia has been stressed more than once and it should therefore be made plain that there are also puzzling differences between the two. This is notably the case with two of what are now characteristic Australian types, *Casuarina* and the Myrtaceae, especially, of course, *Eucalyptus*. Neither of these is prominent in Africa; the Myrtaceae are very poorly represented there even in the tropics, and *Casuarina* does not occur native at all. Yet both are well-developed and characteristic features of the Melanesian tropical flora. Several species of *Eucalyptus* itself occur there, one of which at least is generally regarded as among the least specialized. May it not be, then, that these two genera, doubtless among others, are not in fact Australian types in origin, despite their prominence there to-day, but among the most conspicuous examples of that filling of a partial vacuum, mentioned earlier, by appropriate stocks from Melanesia?

Finally, it must not be forgotten that the sequence of events outlined above presupposes the present latitudinal distribution of climate, which arises from the position of the poles, to have remained unchanged throughout. To have incorporated the possibility that there was at the same time polar movement would have complicated the picture too much, but it must always be remembered that if, as there seems reason to believe, there may have been some such contemporary changes in the positions of the poles, these could have had one of three effects. They could have intensified the climatic changes suggested; they could have reversed them; or they could even have prevented them. They could scarcely, however, have affected the movement of Australia in itself.

---

OBITUARIES

Dr. Emil Abel

Dr. Emil Abel died in London on April 3 in his eighty-third year, after a short illness. He had studied in Vienna and then under Nernst. In 1905 he established himself as *Privatdozent* at the Technische Hochschule in Vienna, and when a chair of physical chemistry was created he was appointed professor and head of the institute attached to the chair. He held this position until the Anschluss in 1938, when he was dismissed under the Nuremberg laws. With his family he found refuge in England; during the War, and for several years after, until his retirement, he was in charge of the research laboratory of the Ever Ready Co., Ltd.

Though he contributed to many branches of physical chemistry, his main interest was chemical kinetics. His early work was devoted to homogeneous catalysis, and he showed in a series of brilliant papers that the role of the catalyst is the creation of additional reaction paths from the reactants to the products. He used to insist firmly that "it is reactions that catalyse, not substances".

After the First World War he turned his attention to the reaction complex of the acids and oxides of nitrogen and sulphur, and contributed a number of papers on the mechanism of the reactions in the lead chamber process for the production of sulphuric acid. He also continued his work on the mechanism of oxidation-reduction reactions and studied the isotope effect in kinetics. During the Second World War he worked on industrial problems of national importance and projected a study of the basic mechanism of the dry cell; he worked on this until his retirement. Even afterwards he did not remain idle: he considered different kinetic mechanisms from a unified point of view in which electron transfer reactions play a central part.

Abel had established a large and vigorous school in Vienna, and his institute produced work on many branches of physical chemistry. He had a peculiar, racy style of lecturing, which was appreciated more by the élite than the average student.

He took little active part in matters outside science, but had by no means the narrow outlook of the specialist; those who had the pleasure of hearing his talks to the Austrian Club in London can testify to this. He had an uncomplicated, pleasant nature; though he continued to live in London after the War, he always had a great love for Austria. His eightieth birthday was the occasion for special celebrations by the Academy of Sciences in Vienna and the Bunsengesellschaft.

His two children of his first marriage, and his second wife, survive him. H. TOMPA

Dr. J. S. Farquharson

THE meteorological service of Great Britain lost a well-known and senior member of its staff, when Dr. James Strachan Farquharson lost his life in a fatal motoring accident on January 31. Dr. Farquharson was born on June 30, 1904, and joined the Meteorological Office in July 1925 after graduation in the University of Aberdeen. He served in various divisions of the Meteorological Office, mainly those concerned with meeting the requirements of civil aviation and the Royal Air Force, both at home and overseas. In June 1954, Dr. Farquharson was appointed as assistant director for public services and, in this capacity, did much to develop both the television and weather broadcasts and the automatic telephone weather service in Britain.

The death of Dr. Farquharson was also a sad loss to the Royal Meteorological Society, of which he had been a Fellow since 1934. As honorary treasurer of the Society, he succeeded in introducing a modification of the old-established policy of investing in gilt-edged securities—a change which he firmly believed will prove of considerable value to the Society. His contributions to the Society's *Quarterly Journal* included two studies related to the development of Empire air routes, namely, "Haboobs and Instability in the Sudan" and "The Diurnal Variation of Wind over Tropical Africa".

The death of Dr. Farquharson has brought to an untimely end an experienced and energetic personality with a wide comprehension of, and original ideas for meeting, the meteorological requirements of the community. R. G. VERYARD

Mr. F. J. Welch

THE death on May 7 of Mr. F. J. Welch, for forty-six years an assistant in the George Holt Physics Laboratory of the University of Liverpool, has severed one of the few remaining links of personal association with Sir Oliver Lodge, Lyon Jones professor of physics in 1900. Mr. Welch was then only in his early twenties, but his recollections of the great man—and his wireless aerial—were very vivid.

Prof. Wilberforce followed Sir Oliver and held the chair for thirty-five years, and Mr. Welch became senior laboratory steward during this period. Those were the days when popular lectures were delivered on "Liquid Air", and also when medical as well as science students attended lectures and demonstrations in physics, which brought them all into intimate contact, not only with the teaching staff, but also with Mr. Welch, who acted as demonstrator. Many physicists, medical men, dentists and school teachers now scattered all over Britain will have happy recollections of the kind and helpful way he always had with them at these classes.

Sir James Chadwick became professor of physics in 1935, and until he retired in 1946, Mr. Welch was in the Department and experienced the period of secrecy which followed the splitting of the atom; and he had close contact with other well-known physicists, such as Prof. J. Rotblat and Prof. O. R. Frisch.

It is interesting to note that his eldest son, E. A. Welch, who received his early training in the George Holt Physics Department, is now senior technician in the Department of Physics, University College of North Wales, Bangor. W. J. PIERCE

Mr. G. A. Cook

MR. GEORGE ALFRED COOK died suddenly in Melbourne on January 4. He had enjoyed a comparatively brief retirement from the Commonwealth Scientific and Industrial Research Organization, of which he had been secretary during 1944–52. Before the First World War, Cook was an outstanding student at Ormond College in the University of Melbourne and graduated with first-class honours as master of science and bachelor of mining engineering. During the War he was commissioned in the Second Australian Tunnellers, in which unit he gave distinguished service in France and was awarded the Military Cross.

After the War he spent several years in research work in the mining industry, and in 1922 joined the Institute of Science and Industry as a scientific abstractor. The Institute was replaced by the Council for Scientific and Industrial Research, which in turn was succeeded by the Commonwealth Scientific and Industrial Research Organization, and Cook's service with these bodies was continuous. When he joined the Institute in 1922 there were only two people with scientific training on the staff. When he retired as secretary of the Organization, there was a total staff of more than three thousand, of whom one thousand held professional qualifications. Cook, during his early years with the Organization, took a particular interest in making the results of scientific research available to industry, both as an editor of scientific publications and as a writer of non-technical accounts for the general reader.

NEWS and VIEWS

Sir Macfarlane Burnet, O.M., F.R.S.

THE award of the Order of Merit to Frank Macfarlane Burnet will delight scientific workers generally and particularly those who labour in Burnet's chosen fields of virology and immunology. Australians will, of course, especially appreciate that this high honour has fallen to one of themselves. For most of his life Burnet has worked in Melbourne, at the Walter and Eliza Hall Institute, and he has been its director since 1944. With his increasing scientific distinction he has had many temptations to accept important positions outside Australia. Perhaps he likes Australia ; in any event, he has resisted all blandishments and his decision to stay there has been of benefit not only to Australia but, indirectly, to the world at large, for he has founded in Melbourne a school which has attracted many students from distant parts. His contributions to knowledge mostly concern fundamental principles in biology ; but others have dealt with problems which have an important Australian aspect to them—*Q*-fever, psittacosis, Murray valley fever and myxomatosis are examples. Burnet is best known for his work on viruses, especially influenza. He and his co-workers have been able to throw important light on the mechanisms whereby viruses become attached to and infect cells. More recently, he has been interested in the nature of antibodies, their mode of formation and of action. Above all, Burnet is an all-round biologist, a master of the 'magnificent generalization'. When men with such rare gifts turn up, they well deserve the highest of honours.

Theoretical Atomic Physics in Copenhagen :

Prof. L. Rosenfeld

PROF. LEON ROSENFELD, who has occupied the chair in theoretical physics in the University of Manchester since 1947, is now leaving to become professor in the new Nordik Institute for Theoretical Atomic Physics at Copenhagen. Prof. Rosenfeld is perhaps now most widely known for his contributions to nuclear physics, where his wide interests are well typified by his book, "Nuclear Forces" (1948), which was one of the first authoritative and comprehensive works in the field of nuclear physics, and for his work as editor of *Nuclear Physics*—the first journal devoted entirely to this field. However, his interests have not been limited to this single branch of physics, nor has his influence been confined to Manchester alone. His earlier work with Niels Bohr on the interpretation of quantum mechanics has been followed by many publications dealing with basic problems in physics, their history and their philosophical implications. His views and influence have been made felt in many parts of the world, not only by his published work, but also by his lectures and personal contacts. For Prof. Rosenfeld, physics, and science generally, is part of a mature, scholarly and cultural outlook, an outlook which was conveyed to, and was appreciated by, audiences in many countries. Prof. Rosenfeld's views and ideas were part of the culture of the civilized world, and although the centre from which they are disseminated will now move from Manchester to Copenhagen, their influence will no doubt be as widespread as ever. In Manchester, as elsewhere, one may hope still to continue to enjoy them.

Theoretical Physics in Manchester :

Dr. B. H. Flowers

DR. BRIAN H. FLOWERS has been appointed to the chair of theoretical physics in Manchester, from which Prof. Rosenfeld resigns this year. Dr. Flowers took the Natural Science Tripos at Cambridge, and then worked at the Atomic Energy Laboratory in Montreal, and after the Second World War joined the newly established Atomic Energy Research Establishment at Harwell. For a time he worked in Prof. Peierls's Department of Mathematical Physics, University of Birmingham, and was awarded a D.Sc. degree by that University. In 1952 he was appointed, at a remarkably early age, to be head of the Theoretical Physics Division at the Atomic Energy Research Establishment, Harwell, and since then he has continued to occupy this very responsible post. Dr. Flowers is widely known for his many outstanding contributions to the theory of nuclear structure and the application of group-theoretical methods to these problems. In his work at Harwell, Dr. Flowers has contributed to many important problems which have arisen in the extensive range of activities covered by nuclear science and atomic energy. His intellectual gifts, his great energy, his wide experience of physical problems and, through his early work, his first-hand appreciation of the problems of experimental physics, will, in addition to his expert knowledge of nuclear physics, all be greatly appreciated at Manchester. Manchester has a long and distinguished tradition in theoretical physics, a tradition which includes Bohr, Eddington, Hartree, Milne and Schuster, as well as Dr. Flowers's immediate predecessor. Dr. Flowers will, without doubt, further enhance this great tradition.

Dr. J. Glasspoole, I.S.O.

DR. J. GLASSPOOLE, a principal scientific officer in the Meteorological Office and well known to all those requiring information regarding the distribution of rainfall in the British Isles, retired at the end of last year after nearly thirty-eight years service. Dr. Glasspoole began his career in the British Rainfall Organization, which was taken over by the Meteorological Office in 1919. Thereafter he was continuously employed on climatological work, especially the study of one particular element, rainfall. He wrote a large number of papers on the subject and became a recognized authority on the incidence and distribution of rainfall in the British Isles. In recognition of his services, he was appointed a Companion of the Imperial Service Order, and the Institution of Water Engineers made him an honorary member of the Institution.

The Scientific American

IN January 1948, the editing and publishing of *The Scientific American* (415 Madison Avenue, New York, 17), one of the oldest of America's scientific journals (founded in 1845), was taken over by Mr. Gerard Piel and his two partners, Mr. Dennis Flanagan and Mr. Donald H. Miller, jun. At that time, the journal was being far from successful, since only about two thousand copies of each issue were paid for in cash, and advertising revenue was quite negligible. During the past ten years, however, *The Scientific American* has undergone a metamorphosis which may be described as staggering, for now it has more than two hundred thousand monthly subscribers on its books. Mr. Piel, publisher, and his colleagues are to be congratulated on this great achievement, especially since, through sound policy, good editing and attractive presentation this journal has won the high regard of scientists and laymen alike for its excellent interpretation of scientific discoveries and advancement.

All the articles which appear in *The Scientific American* are authoritative, being written by men of science directly concerned with the work being reported —usually leading authorities themselves. In the past, these have included Einstein, Karl Compton, Robert Oppenheimer and Hans Bethe. But these articles are rigorously edited with the view of clarification, not simplification. The journal is lavish with its illustrations—photographs, drawings, charts and diagrams, many of which are coloured. But the editors make sure that the text shall not become a mere vehicle for attractive pictures. The aim of the latter is to give the reader a vivid grasp of what the article is about and to develop the relationships between variables which so often defy exposition by the written word. So fine, rather than commercial, artists are employed because, as the publisher claims, "The creative artist, when he turns his interest to science, tends to come up with really original solutions to the problems presented by the text".

In connexion with *The Scientific American*, ten paper-backed topical 'anthologies' have also been published, and the aim is to issue about five of these every eighteen months. These 'anthologies' have already been translated into a dozen languages.

Here is a very successful venture into scientific literature for which all scientific workers and especially non-scientific readers must be very grateful. To mark the tenth year of publication under its new direction, a "Cumulative Index" (author, title and subject) of all the issues of this magazine from its first issue (May 1948) to 1957 is now available. We take this opportunity of congratulating the board of editors, including Mr. Gerard Piel (publisher), Mr. Dennis Flanagan (editor) and Mr. Leon Svirsky ; the art director, Mr. James Grunbaum ; the general manager, Mr. Donald Miller, jun. ; and the advertising manager, Mr. Martin M. Davidson, on their magnificent achievement. They are making a first-class and essential contribution to the advancement of science.

Medical Colour Television

On June 4 the first mobile medical colour television unit to be designed and manufactured in Great Britain was handed over by the Marconi's Wireless Telegraph Co., Ltd., to Smith, Kline and French Laboratories, pharmaceutical manufacturers, who ordered the equipment. The vehicle weighs 6 tons, and the television apparatus accounts for a further 2 tons. The available space has been divided into three sections. The rear compartment is staffed by one maintenance engineer to service the apparatus, which combines the red, green and blue signals for transmission via land-line or microwave link. The technical director, the vision mixer, the sound mixer and two camera-control operators work in the centre compartment under the control of the producer. This room houses a colour monitor for each camera, and a third one acts as a line monitor. These are fixed to a monorail, so that they can be moved to either of the other two sections for maintenance or repair. The driver's compartment is also used as a servicing area. The cameras are direct descendants of those supplied to the British Broadcasting Corporation a few years ago. The display unit is a Marconi Colour Television Projection Unit, which can provide a picture 8 ft. × 6 ft., which is said to be adequate for viewing by an audience of up to 300. This equipment will be made available, without charge, to conferences and congresses, so that large audiences can obtain a close-up view of operations or clinical demonstrations. A two-way radio link is provided to facilitate discussion between the surgeon or demonstrator and the audience.

Smoking and Lung Cancer

Following the decision of the Ministry of Health to accept the Medical Research Council's findings as establishing a causal relationship between smoking and lung cancer, local authorities were asked to promote appropriate educational campaigns. The Central Council for Health Education was recommended as a suitable agency. To help local authorities, Dr. John Burton, director of the Central Council for Health Education, has produced a summary of the relevant medical and ethical issues which should be considered by local authorities before launching its campaign. It includes the essential facts about lung cancer ; criticism of the facts ; other factors involved for which there is some evidence ; facts about smoking ; reasons for and attitudes to smoking ; giving up smoking ; policy on presentation of the case against smoking ; aims and methods of presenting the facts ; and the questions people ask. The summary is a clear, objective, factual account of the relationship between smoking and lung cancer and should give local authorities the kind of lead for which so many of them have been asking.

Language and Speech

Interest in the problems of language and speech has grown rapidly in recent years. In this, the biggest single factor is undoubtedly modern communications engineering and its impact upon the biological sciences. New electro-acoustic techniques have thrown much light on the physical basis of speech and are being increasingly applied to the study of fundamental problems in experimental psychology. The theory of information, as developed by Shannon and others, would appear to have important application to biological systems, not excluding the field of human behaviour. Furthermore, recent developments in statistical technique have given promise of a new and more genuinely scientific approach to linguistics. In view of these considerations, any serious attempt to bring together the many and diverse approaches to the study of speech deserves a warm welcome. *Language and Speech* is a new quarterly edited by Dr. D. B. Fry, of the Department of Phonetics, University College, London (annual subscription : 80*s*. ; 11.50 dollars. Single issues : 25*s*. ; 4 dollars. Teddington, Middlesex : Robert Draper, Ltd., 1958). Its avowed purpose is ". . . to furnish a medium for publications in which the fundamental problems of speech and language form the centre of interest". It is to offer space not only for reports of experimental findings but also for discussion of theoretical issues arising from, or relevant to, experiment. The fields covered include language structure, the transmission and reception of speech, mechanical translation, synthetic speech, and abnormalities of speech and language. Of particular interest in the first number (1, Part 1; January–March 1958. Pp. ii+78) is a paper on brain disorders and language analysis by Prof. A. R. Luria, of the University of Moscow.

A Folk-lore Survey

IN the *Museums Journal* of May, Mr. J. M. Dodgson describes in detail the procedure adopted in connexion with a survey of English folk-lore which he is carrying out from University College, London. The object of the survey is a classified index of English folk-traditions, comparable with that of Swedish folk-lore in Sweden or of Irish and Scottish folk-lore in Dublin and Edinburgh. The survey is being conducted in a scholarly and critical manner and is an attempt to reduce to methodical order a subject which up to the present has not been dealt with on a scientific basis. The co-operation of museum curators is invited, and Mr. Dodgson looks forward to the time when every district of England will possess a well-ordered folk museum.

Federation of British Industries

THE forty-first annual report of the Federation of British Industries, covering the year ended December 31, 1957 (pp. vi+43. London: Federation of British Industries, 1958), displays the wide range of the Federation's interests. During 1957 the Federation continued to be greatly interested in the problems involved in Britain's possible entry into a European Free Trade Area, and its studies of the implications of this proposal led to a general survey for industrialists and a joint report, with the Association of British Chemical Manufacturers and the National Union of Manufacturers, to the Government on the kind of convention it should seek in the negotiations for a Free Trade Area, and a study of comparative taxation in European countries. In November the Grand Council of the Federation finally recorded its opinion as being, on balance, in favour of the Government's policy, provided certain safeguards and conditions were secured. Evidence was submitted to the Radcliffe Committee inquiring into the working of the monetary and credit system, and to the Trade Effluents Sub-Committee of the Central Advisory Water Committee, which is considering the law affecting the disposal from trade premises of liquid effluents; much statistical information was collected for another sub-committee considering the growing demands for water, and the Federation pioneered a scheme whereby the Department of Scientific and Industrial Research will undertake, on behalf of industry, research on the fundamental problems of the treatment and disposal of trade wastes and the purity of rivers. In education, links with the universities, technical colleges and schools were further consolidated, and a memorandum submitted to the Minister of Education in August supported particularly the proposal of the Willis Jackson Committee for a staff college for senior teaching staffs in technical colleges. Among topics considered by the Industrial Research Committee were the establishment of a National Lending Library for Science and Technology and British official overseas scientific representation.

Scaling-up of Chemical Plant

THE Institution of Chemical Engineers, in co-operation with the Chemical Engineering Group of the Society for Chemical Industry and two similar Dutch organizations, arranged a two-day symposium in London in May 1957 on "The Scaling-up of Chemical Plant and Processes". Previously, the literature on the subject had been very scanty, but the recent text-book by Johnstone and Thring (see *Nature*, 181, 1094; 1958) and the proceedings of the symposium (pp. 136. London: Institution of Chemical Engineers, 1958. 60*s*.) together form a sound basis for a study of the subject. One of the major decisions to be taken in developing a new process is whether or not to carry out pilot-plant tests and how best to interpret the information so obtained. The papers presented at the symposium cover a wide field and illustrate many of the problems involved. The first session was devoted to fundamental aspects: introductory ideas on scaling-up and the principles of similarity are discussed, together with the design of reactors, with special reference to the economics of batch, tubular and continuously stirred tank reactors. The first session ended with a discussion on the relation between the cost and the size of plant. The following three sessions were devoted to scaling problems related to specific processes and equipment, including the rotating-disk contactor, cyclones, air-separation plant, continuous-filtration equipment, and solvent extraction and gas absorption. The discussion at the end of each session is also reported. About 60 per cent of the papers were from England and 40 per cent from Holland.

Pharmacopœias, Dispensatories and Formularies

HUMAN societies, as it seems, have long had an inherent urge towards the possession of a *materia medica*. In this connexion, the biological journal, *Lloydia* (20, 1; 1957. Lloyd Library and Museum, Cincinnati, Ohio), contains an article of somewhat unusual interest, namely, "A Catalogue of the Pharmacopœias, Dispensatories, Formularies, and Allied Publications (1493–1957) in Lloyd Library". As the authors explain, John Uri Lloyd, who founded the library in 1864, began to collect these literary materials in the same year. This effort has evidently been continued with zeal, so that the collection now contains more than 1,000 titles, dating from 1493 to the present time, from all parts of the world. The arrangement of the catalogue is alphabetical by countries and chronological by dates of publication. Among the illustrations, one may note reproductions of the title pages of such works as "Pharmacopœa Dogmaticorum Restituta" (Paris, 1607) and "Pharmacopœa Persica" (Paris, 1681).

Metabolism of Marine Flagellates

THE products of photosynthesis of two marine flagellates have been examined and compared with those of *Chlorella pyrenoidosa* with the use of radioactive carbon and chromatographic techniques by R. G. S. Bidwell (*Canad. J. Bot.*, 35, 945; 1957). The alcohol-soluble products were different in each alga, many of the compounds produced by the marine forms being unidentified. The principal soluble product of photosynthesis of a member of the Heterokontae, *Olisthodiscus* sp., was identified as *d*-mannitol. Those of a dinoflagellate, *Amphidinium carteri*, include glycosides of glucose and mannitol. The main insoluble carbohydrate produced by all three organisms gave rise to glucose on hydrolysis; this only contained about 10 per cent of the total fixed carbon. The radioactive compounds released from the alcohol-insoluble residues by acid hydrolysis were similar in the three algae and consisted mainly of amino-acids.

Electron Density Profiles in the Ionosphere

In many parts of the world during the past twenty years, regular measurements have been made of the maximum electron density (N_m) and the approximate true height (h_m) of the various layers in the ionosphere. Both these parameters can be obtained fairly easily from the $h'(f)$ curves (ionograms) which are produced by automatic pulse-sounding equipment. On the other hand, very little accurate information is available on $N(h)$ profiles, the distribution of electron density with height in the ionosphere, and how these profiles vary with time, season and geographical location. Correspondingly, little is known about the variation of electron density with time at a constant height (the $N(t)$ curve). The ionograms contain all this information, but the mathematical procedure for deriving it explicitly is very laborious, especially if the effect of the geomagnetic field is taken into account. The electronic computers now available have opened up a new era in this field since they can readily be used to compute $N(h)$ profiles from ionograms.

A programme of such computations has been organized by the Radio Research Station of the Department of Scientific and Industrial Research, at Slough, as part of the United Kingdom programme of observations during the International Geophysical Year. The $N(h)$ profiles are being produced by Ferranti, Ltd., on a "Pegasus" automatic digital computer using $h'(f)$ data obtained at four observatories, namely, Slough, Ibadan, Singapore, and Port Stanley. For each observatory profiles are being calculated for each hour of the day for about four days a month beginning in July 1957. When the ionograms are suitable, Regular World Days are selected for analysis; when this is not practicable, other days are substituted. This programme will be continued until December 1958 when the possibility of extending the work will be considered. The analysis is carried out according to a method recently described by Thomas, Haselgrove and Robbins (*J. Atmos. Terr. Phys.*, 13, 46; 1958), which makes no *a priori* assumptions about the variation of electron density with height except that it increases monotonically. It can be applied to $h'(f)$ curves from any observatory merely by changing the geomagnetic dip angle and the gyro-frequency, both of which are taken into account in the calculations.

The Association of Universities of the British Commonwealth

The report for 1956–57 of the Executive Council of the Association of Universities of the British Commonwealth (pp. 25. London, 1958), to which are appended a note on the Committee of Vice-Chancellors and Principals of the Universities of the United Kingdom (which met eleven times during the year) and the accounts of the Association, records expenditure of £24,797 and an income of only £26,980 compared with £27,860 for 1955–56. Lists of names and other particulars of overseas students continued to be collected from all universities and university colleges in the United Kingdom and a statistical analysis of this material has been printed as an appendix to the Commonwealth Universities Year Book for 1958. These lists are available for consultation by accredited inquirers and the Association also maintains a collection of up-to-date issues of official publications of Commonwealth universities, which are available in the office for reference by inquirers. During the year the Association acted in connexion with 408 appointments in member universities outside the United Kingdom, compared with 394 in 1955–56, and handled 2,871 inquiries in relation to specific vacancies, compared with 2,962 in 1955–56. A list of posts in respect of which the Association was requested to take action is included. The Association has also assisted in the administration of the Marshall Scholarships, the Beaverbrook Scholarships, the Commonwealth University Interchange and in the award of British Memorial Scholarships for study in Australia and Imperial Relations Trust Fellowships.

European Interchange Scheme for Postgraduate Students

The Department of Scientific and Industrial Research is encouraging the interchange of research students between the United Kingdom and certain European countries, and has set aside a number of its research studentships for this purpose. Those awarded such studentships for study in Europe will receive maintenance allowances, second-class rail fare and fees; in addition, a cost-of-living allowance will be paid for certain countries. The award is tax-free. The duration of the award, and other conditions, are the same as those for ordinary Department of Scientific and Industrial Research studentships. Applications for these awards must be made through heads of departments of science and technology in universities and colleges before July 1.

Grants to Students

The National Union of Students has published a Grants Year Book (pp. 107. London: National Union of Students, 1958. 3*s*.) giving details of awards to students by nearly all the local education authorities of Great Britain. Besides information about the scale of awards, allowances for vacations and dependants, the book also provides details of how awards are made, the policies of local education authorities to students who fail examinations and other relevant items. A copy of the Ministry of Education Regulations for State Scholarships is also included; this sets out the income scale for assessing parental contributions. The book should be of practical value to all students and their parents or guardians.

The Salters' Institute of Industrial Chemistry

The Worshipful Company of Salters, through its Institute of Industrial Chemistry, has since the foundation of the Institute in 1918 devoted its resources mainly to the award of postgraduate research grants. Ninety-eight research students have been awarded fellowships and most of them have had distinguished careers in industry and the universities. In 1951 the award of a research scholarship was instituted, and twenty-eight students have since been elected, including three to scholarships reserved for students from the Commonwealth. A considerable number of smaller grants have also been awarded each year to part-time students of chemistry in London, and many of the chemical engineering departments of universities throughout Britain have received substantial grants for the purchase of equipment or similar purposes. Arrangements have now been made with the Royal Institution for the Company to sponsor lectures to school-children in some of the interesting branches of chemistry, on the lines of the lectures on physics which have been given there with such success in recent years. The Institute has also decided to make grants to headmasters of selected public schools from which Salters' Exhibitions may be awarded to able boys who might otherwise be unable to complete a scientific education. By these new developments, the Institute hopes that the study of science in schools may be enlivened and encouraged and that indirectly the flow of scientists of high calibre to the universities and eventually to industry and other fields may be increased.

Royal Netherlands Geographical Society : Honorary Members

The following have been elected to honorary membership of the Royal Netherlands Geographical Society: Prof. J. Büdel, University of Würzberg, distinguished for his researches on peri-glacial phenomena and on the morphology of the humid tropics; Prof. H. C. Darby, University of London, author of "A Historical Geography of England" and "Medieval Fenland and the Draining of the Fens"; G. J. A. Mulder, Netherlands, author of various text-books on geography including "Geography of the Mediterranean Region" and editor-in-chief of the "Manual of Geography of the Netherlands".

The Manchester Literary and Philosophical Society: Officers

At the recent annual general meeting of the Manchester Literary and Philosophical Society the following officers were elected: *President*, Mr. C. E. Young; *Vice-Presidents*, Miss A. C. Alexander, Mr. A. H. Goulty, Sir Geoffrey Jefferson, Dr. F. C. Toy; *Hon. Secretaries*, Dr. G. T. Ashley, Dr. L. Cohen; *Hon. Treasurer*, Mr. H. Hayhurst; *Hon. Librarians*, Mr. L. L. Ardern, Dr. W. H. Brindley; *Hon. Curator*, Mr. N. G. C. Pearson.

The Night Sky in July

Full moon occurs on July 1d. 06h. 04m. U.T., new moon on July 16d. 18h. 33m. and full moon on July 30d. 16h. 47m. The following conjunctions with the Moon take place: July 9d. 15h., Mars 3° S.; July 14d. 06h., Venus 3° N.; July 23d. 04h., Jupiter 2° N.; July 27d. 03h., Saturn 3° S. In addition to these conjunctions with the Moon, Mercury is in conjunction with Pollux on July 1d. 11h., Mercury being 4·9° S., Venus with Aldebaran on July 5d. 06h., Venus being 4·0° N., and Mercury with Regulus on July 26d. 05h., Mercury being 1·6° S. Mercury is an evening star, setting about an hour after the Sun, but conditions are not favourable for observation. Venus is a morning star, visible low in the south-east before sunrise. It rises at 1h. 55m., 1h. 50m. and 2h. 10m. on July 1, 15 and 31, respectively; its stellar magnitude is −3·3. During the month its distance from the Earth increases from 120 to 137 million miles and the visible portion of the apparent disk from 0·812 to 0·890. Mars rises at 0h. 10m., 23h. 30m. and 22h. 50m. at the beginning, middle and end of the month, respectively; conditions for observation are rapidly becoming more favourable. Its stellar magnitude increases during the month from +0·3 to −0·1, its distance from the Earth decreasing from 101 to 86 million miles. Mars continues to move eastwards among the stars, passing from Pisces to Aries on July 26. Jupiter sets at 0h. 10m., 23h. 15m. and 22h. 10m. on July 1, 15 and 31, respectively; it is near Spica. The stellar magnitude of Jupiter is −1·6, its distance from the Earth on July 15 being 500 million miles. Saturn sets at 2h. 45m., 1h. 45m. and 0h. 35m. at the beginning, middle and end of the month, respectively; it is near θ Ophiuchi. It has a stellar magnitude of +0·4 and a distance of 850 million miles from the Earth on July 15. There is one occultation of a star brighter than magnitude 6 visible at Greenwich: July 24d. 21h. 05·8m., ν Lib. (disappearance). The Earth is at aphelion on July 5, its distance from the Sun being 94·6 million miles.

Announcements

The British Overseas Mining Association Educational Trust has been established by the Association to provide scholarships tenable at mining schools and universities in the United Kingdom for courses in mining engineering and related subjects. Further information can be obtained from the Secretary of the Association, 8 Great Winchester Street, London, E.C.2.

The Oliver Memorial Fund is offering an award of £50 to a British subject for original work or services in connexion with the research, organization or donor aspects of blood transfusion. Applications or information on possible candidates for the award should be sent to the honorary secretary, Mrs. F. E. Bedborough, 105 New Park Avenue, London, N.13.

The thirteenth annual exhibition and convention organized by the Northern Division of the Institution of Electronics will be held at the Manchester College of Science and Technology during July 10–16 (excluding Sunday, July 13). It will include the largest British display of electronic devices held outside London.

A one-day meeting of the Polarographic Society will be held at Ardeer, Ayrshire, on September 26, by kind permission of Imperial Chemical Industries, Ltd. Further information can be obtained from Mr. A. F. Williams, Research Department, Imperial Chemical Industries, Ltd., Nobel Division, Stevenston, Ayrshire.

A conference on Mass Spectrometry is being organized by the Mass Spectrometry Panel of the Institute of Petroleum Hydrocarbon Research Group and Committee *E*-14 of the American Society for Testing Materials. It will be held in the Beveridge Hall, Senate House, University of London, Gower Street, London, W.C.1, during September 24–26. Further information can be obtained from Dr. R. R. Gordon, National Coal Board, Coal Research Establishment, Stoke Orchard, Cheltenham, Gloucestershire.

The seventh Conference on Hot Laboratories and Equipment is to be held in Cleveland, Ohio, during April 1959. Abstracts of papers to be presented at the Conference should be sent to the programme chairman, L. G. Stang, jun., Brookhaven National Laboratory, Upton, New York, before September 15. Papers are invited on all phases of hot laboratories and equipment for handling radioactive material, including design, construction, operation, maintenance, decontamination, remodelling, shielding calculations, costs, etc.

Erratum. In the communication entitled "Passage of Phosphate through the Human Tooth", by Dr. P. Pincus, in *Nature* of March 22, p. 844, paragraphs 5 and 6, for "inorganic phosphate" and "inorganic form" read "organic phosphate" and "organic form".

INDUSTRIAL PSYCHOLOGY

AN outline of the history and work of the Medical Research Council's Industrial Psychology Research Group, since its origin (under another name) in 1918, has recently been provided by R. Marriott, assistant director of the Group (*Occupational Psychology*, 32, No. 1; January 1958).

Between 1918 and 1947 more than a hundred reports and many papers were published. Broadly speaking, the wide range of subjects covered could be classified under the general headings of environmental conditions (lighting, vision, heating and ventilation), the effect of industrial solvents, industrial disease, sickness and absence, hours of work, repetitive work, human relations, vocational psychology, time and motion study, accidents, skill and machine design.

After the Second World War it was decided to bring the existing teams into line with other units or groups of the Medical Research Council by making them self-contained and directly responsible to the Council for their activities. Two of these teams had been mainly responsible for most of the psychological investigations. One, the Applied Psychology Unit at Cambridge, had done much work on accidents, environmental conditions, skill and machine design. The other team, under the direction of Dr. S. Wyatt, had been mostly concerned with such problems as absence from work, motivation and incentives, interest and boredom in work, and satisfaction and discontent in the working situation. This team became the Industrial Psychology Research Group with Dr. Wyatt as its first director. In 1952 the Group was transferred to University College, London, under the honorary direction of Prof. R. W. Russell and Mr. J. W. Whitfield, of the Department of Psychology.

During 1946–52 the Group's two teams, with from four to six investigators in each, were mostly occupied with comparative studies of the nature, extent and causes of satisfaction and discontent in various types of large industrial organizations. The published papers show, for example, clear-cut relationships between working efficiency and size of group and between satisfaction and size of group. They also demonstrate that workers' satisfaction is correlated with the amount of mechanization in the layout. Thus, those on mechanized layouts are less satisfied and express more boredom than those on non-conveyor-line work; individual workers are the most satisfied and least bored. Satisfaction with earnings was related to family responsibilities, and general satisfaction to various factors such as hours of work, shift systems and management policy.

Since 1953 most of the research done by the Group has been concerned with three general problems—absence in heavy industry, communication within industrial firms, and incentive payment systems. Final reports on these projects have not yet been published, but some papers and abstracts bearing on the investigations are available. The following are brief outlines of the methods used and the main conclusions.

A survey was made of the absences of three thousand men in one engineering and two large iron and steel works. Absence from all causes was compared for such factors as age, family responsibilities, length of service, wages, hours of work and physical conditions.

It was found, in general, that absence was least from men with two dependants and higher for those with fewer or more—the curve was U-shaped; higher paid men lost more time due mainly to sickness but partly to absence without permission; absence was associated with heaviness of work, the trend being more pronounced for short absences and among men on continuous work. Continuous work also appeared to cause more absence among men more than forty-five years of age; on three-shift systems about three-quarters of the absence without permission occurred on the early morning shift, due, it was thought, to the 6 a.m. start.

Three studies were made under the heading of communication in industry, one in the laboratory and two in factories.

The experimental study sought to compare the relative understanding and retention of salient points in a prose passage (uncompressed information) and in a précis of it (compressed information). Pilot studies showed that recall, not recognition, of the material was the most successful method of discriminating between the two kinds of information.

Studies in four engineering firms were made, by interviews, observation and the analysis of records, of the differences in formal communication structures in planning and production control, and in particular of their effects on the estimating of delivery dates to customer firms. Differences between the firms in these respects were mainly in the degree of integration between planning and control. On this depends the adequacy and accuracy of the estimator's knowledge of the results of his decisions. It was found that more accurate estimates were made and greater satisfaction was expressed where there was unity of planning and control; the opposite was true where these two functions were divided.

Another inquiry showed that, in general, delivery time was twice as long as the time allowed for production; only 2 per cent of the orders took less than the expected time; 80 per cent of the delay occurred during normal production and 20 per cent in rectification work. The 80 per cent normal production delay was analysed as 9 per cent in supplying materials, 9 per cent in routing between departments, 30 per cent in a capacity block in one department, 15 per cent in the planning and pre-production departments and 17 per cent in other production departments.

Though the analysis of the results is still incomplete, it can be stated tentatively that production control failure, not technical breakdown, was mainly responsible for the total delay.

Recent research into incentive payment systems has taken the form of four separate studies which, although conceived as parts of the whole, were carried out to a large extent independently of each other, as well as a review of research and opinion on incentive payment systems.

Two of these studies were general field surveys relating to workers' understanding of incentive payment systems and to the aims associated with the introduction of such systems. The other two studies concerned the effects of changes in incentive payment systems in a factory and a repair works. All the studies showed the importance of considering the total factory situation, the relevance of the incentive payment system to the nature and organization of the work, and the social effects produced by these systems.

Satisfaction with a system appeared to be related to the understanding of it, and this depended on the workers' ability to explain it to themselves.

In the two studies of changes in payment systems it was found that improved morale and satisfaction followed the change, but it was not possible to attribute this to the alteration alone. There was evidence that improved output may accompany increased satisfaction, but different performances by comparable working groups were attributed more to the size and stability of the groups. Social conflicts arose in group systems if there was equal regard for unequal effort.

In addition to these investigations, essential incidental studies have been carried out on methodological problems in order to facilitate work in this field. Among these are a study of the dangers of using crude absence-rates available in industry; examinations of the use of linear and verbal self-assessment scales in the assessment of attitude; consideration of possible extensions of the paired comparison technique in measurement of opinion and in measurement of agreement of opinion; a study of the different methods of measuring understanding and remembering of verbal material and the development of rank correlation methods.

Papers have also been published on accidents in industry, and on the effects on skill and performance of machine design, environment and technological change.

CONTACT STRESSES

So many engineering devices, such as toothed gears, rolling bearings and the wheel itself, operate by the transmission of large forces between surfaces in contact over a relatively small area that a knowledge of the local stresses set up in the region of such contacts is obviously of wide interest. Yet the symposium, organized by the Stress Analysis Group and held at the Institute of Physics on May 14, appears to have been the first in Britain to be devoted specifically to the topic of "Contact Stresses". An explanation for the neglect of the subject probably lies in the mathematical difficulties involved in obtaining a theoretical solution to even the simplest problem in contact stress. Apart from the inspired, and now classical, theory of elastic contact presented by Hertz in 1881, there have been until recently very few contributions to the theoretical structure of the subject so beloved of academic investigators. In consequence, the engineering designer has been obliged to develop his own empirical rules and to conduct his own comparative tests to avoid the undesirable consequences of excessive contact stresses: pitting, scuffing, fretting or simple wear.

The past few years, however, have seen considerable advances in the theory of contact stresses. A number of solutions have been found, arising, as so often is the case, from investigations in other fields, to the problem of contact of both ideally elastic and ideally plastic solids under the action of various systems of forces. The basis for more fundamental and revealing studies of the mechanism of surface breakdown under contact loads appears to have been laid, and it is likely that more satisfactory explanations of pitting and other surface failures are not too remote. Even the study of metallic friction and wear, which has attracted scientific work of high quality over a number of years, has benefited from recent theoretical studies.

The present symposium gave encouraging evidence of this trend. The extent to which the problems are common ones was striking. Speakers whose papers arose from interests as diverse as railways, toothed gearing, ball-bearings and rubber tyres described phenomena which were basically similar and to which the academic contributions were relevant.

Contact-stress problems can be divided broadly into two categories, one of contact between surfaces having no relative movement, and the other to include contact between rolling or sliding solids. The first session was devoted to stationary contact, and naturally the papers were concerned with various extensions to the Hertz problem of two ideally elastic bodies under the action of a purely normal force. Mr. C. Storey (Constructors—John Brown, Ltd., Leatherhead) recalled Hertz's assumption that the undeformed profile of the solids in contact could be taken to be parabolic, and showed how the theory could be improved for spherical surfaces. The correction appears to be significant only where there is close conformity between the surfaces, as for a ball-ended pivot in a spherical seating.

Perhaps the most valuable recent contribution to elastic contact theory is due to Mindlin[1] and his associates, who have found the surface tractions and displacements at a contact where a tangential force and a twisting couple are applied in addition to a normal force. They have shown that in consequence some slip is inevitable at a periphery of the contact area. Explicit calculations of the internal stresses in these circumstances have not been made, so that the experimental work of Mr. E. Ollerton (Nottingham) is particularly valuable. He described a photoelastic investigation of the contact stress-field under the action of a normal and tangential force (less than the limiting friction force). The observations with a two-dimensional model as the tangential force approached its limiting value were shown to compare favourably with the theoretical analysis of Poritsky[2]. With smaller tangential forces and also with a three-dimensional model, an attempt was made to deduce the surface stresses to compare with Mindlin's theory, but at the present stage of development of the technique the comparison is rather inconclusive.

The work of Bowden and Tabor[3] on metallic friction has shown that the intimate contact of metal surfaces is to a large extent a plastic phenomenon. In the most lightly loaded contacts the surface asperities are crushed plastically so that the subsequent application of a tangential force, however small, must cause further plastic flow. Dr. D. Tabor

(Cambridge) discussed this process, referring to the experiments on adhesion carried out by McFarlane and Tabor[4] and to the measurements of initial tangential displacement by Courtney-Pratt and Eisner[5]. In both these investigations the behaviour of a single asperity was simulated by using small, heavily loaded contacts in soft metals so that their real and apparent areas of contact coincided. The application of a tangential force to a contact already stressed to the yield pressure in compression causes an immediate increase in the area of real contact. The predominant plastic deformation, therefore, initially brings the surfaces closer together, while the tangential displacements are of an elastic order of magnitude, as their agreement with Mindlin's elastic theory shows. As the tangential force is increased, the contact undergoes large, irreversible, plastic deformation in the tangential direction until, at a point determined by the cleanliness of the surfaces, the junction breaks, and complete sliding occurs. In the context of a meeting on contact stresses it is relevant to ask how the essentially plastic behaviour of individual surface asperities can be related to the overall properties of a contact in which the forces are transmitted through a large number of asperities, while the main body of the material is stressed within its elastic limit—the usual situation found in engineering practice. Is an elastic theory of any value? The experiments of Johnson[6] suggest that the deformation of the contact as a whole can be predicted very closely by an elastic theory. The explanation seems to lie in the fact that if contact is maintained through a large number of junctions their tangential plastic deformation is 'controlled' (in the sense used in plasticity theory) by the strains in the hinterland which remain elastic. Thus two solids first pressed into apparently elastic contact and then sheared undergo normal and tangential displacements given by Mindlin's theory. Over the central area of contact, where the normal pressure is high and the tangential tractions low, the solids are locked together. Towards the edges of the contact area, where Mindlin predicted slip, the asperities may be expected to shear plastically in the manner of Courtney-Pratt's model, through a displacement sufficient (yet no more than sufficient) to relieve otherwise infinite elastic stresses in the body of the material.

The second session was devoted to papers on rolling contact. Experimental investigations of the tangential stresses and relative movements at the contact surface of a rolling pneumatic tyre were reviewed by Mr. V. E. Gough (Dunlop Rubber Co., Ltd., Birmingham). The importance of tangential surface stresses was emphasized since these provide both the driving force and also the controlling forces of a wheeled vehicle. The amount of slip between the tyre and the ground determines the wear-life of the tyre. It was shown that the area of contact is divided into two regions: a forward region where there is no relative movement with the ground, and a region at the sides and trailing edge of the contact area where slip occurs. If the plane of the wheel is inclined at an angle to the direction of rolling, which would arise from the side-slip when rounding a corner, the tangential tractions at the contact surface provide a transverse 'cornering' force. In addition, due to the fact that the slip occurs at the rear of the contact area, this force exerts a self-aligning torque tending to rotate the plane of the wheel into the direction of rolling. Measurements of the cornering force and self-aligning torque as a function of the slip (or yaw) angle show that these quantities increase in proportion to the slip for small angles to a maximum value, after which they decrease gradually. The maximum value corresponds to the transition from partial slip to complete sliding of the tyre on the ground.

The similarity in behaviour of a rolling tyre and a rolling solid is striking. In a later paper, Dr. K. L. Johnson (Cambridge) showed pictures of the contact area of a solid rubber ball rolling on a 'Perspex' sheet. The patterns of slip are almost identical: slip begins at the sides and trailing edge and spreads forwards as the tangential tractions are increased. Experiments with steel balls rolling on steel tracks exhibit similar relationships between the slip motion, or 'creep' as it is frequently called, and the tangential forces and twisting moments. Conditions similar to those obtaining in the case of a tyre rounding a corner occur in angular-contact ball-bearings, where, due to rolling around a curved track, the balls have an angular velocity of 'spin' relative to the races on which they roll, and tangential forces are brought into play by virtue of the 'creep' motion. It follows that in such a bearing the steady-state rolling path of the balls lies between surfaces of the races which are not parallel at the two points of contact, a result which is contrary to the usual assumption in ball-bearing design.

Messrs. A. A. Milne and A. M. Nicholson (Mechanical Engineering Research Laboratory, Glasgow) and also Dr. A. W. Crook (Associated Electrical Industries, Ltd., Aldermaston) were indirectly interested in the life of rolling contacts—the former in rolling bearings and the latter in toothed gears—so that their papers dealt with the breakdown of the rolling surfaces under the continuous application of heavy loads. Milne and Nicholson described some experiments using a modified four-ball machine[7] in which a single rotating ball rolls on three others. The kinematics of the motion were analysed and it was shown that there is a large angular velocity of spin between the rotating and the rolling balls, in consequence of which slip occurs at the sides of the contact area. The majority of the pitting cracks are observed at the edges of the rolling track and on the slower moving surface. The conclusion that, where rolling is accompanied by sliding or even local slip, pitting is more likely to affect the slower moving surface now seems to be fairly well established. As Mr. Milne observed, the cycle of stress experienced by the slower moving surface is one of tension followed by compression, which is consistent with the theory of crack propagation by trapped lubricant proposed by Way[8].

The paper by Dr. Crook suggested that another significant mechanism might be involved. Experiments on rolling mild steel disks under loads sufficiently large to exaggerate the amount of plastic flow were described[9]. He showed that two disks rolling under a purely normal contact force produce plastic shearing of a relatively undeformed surface layer, forward, in the direction of rolling, relative to the main body of the disk. The effect is independent of the presence of a lubricant. Running the disks at different speeds introduces frictional tractions at the contact surfaces, acting in the direction of rolling on the slower surface and opposed to it on the faster one. The effect of these tractions, as might be expected, is to accentuate the plastic flow of the slower surface and restrict or reverse that of the upper surface depending upon the coefficient of friction. In any event, it appears that the slower moving surface experiences much larger plastic deformations than the faster one, which under lighter loads and with less ductile materials would be likely to lead to a shorter fatigue life.

The papers on rolling contact made it clear that stresses and distortions in rolling contact are likely to differ from those in a stationary contact under the same forces. Dr. Johnson explained this difference in terms of the different stress history of a surface element in the two cases. If either slip or plastic flow takes place, a difference in sequence of loading leads to a difference in the overall stress pattern. In particular, it was shown that slip at the contact surface begins at the trailing edge of the contact area and not at the leading edge. A method of approach to the theoretical problems of rolling contact was suggested in which the process is viewed as one of 'steady-flow' in the manner of hydrodynamics. This involves using the Eulerian co-ordinate system[10] in which the contact region appears as a stationary pattern of elastic distortion through which the material of both surfaces flows at a steady rate.

Taken as a whole, the symposium gave a valuable co-ordinated view of the present state of research into contact problems in Britain. K. L. JOHNSON

THE METROPOLITAN-VICKERS IRRADIATION LABORATORY

THE opening on May 29 of the new Irradiation Laboratory at the Metropolitan-Vickers Barton works was performed by Mr. H. West, director of electrical engineering in the Company. In a short address he reminded his audience that the scientific and engineering contributions made by Metropolitan-Vickers to the development of high-vacuum equipment and particle accelerators have been prominent in keeping Britain to the forefront in this field. An inspection of the new laboratory certainly gave strong support to his claim.

The principal item of equipment in the laboratory is the 4-MeV. linear accelerator, which produces the beam of irradiating electrons. There is nothing fundamentally new about this unit; it has been adapted from the accelerator developed by the Company for its 4-MeV. X-ray machines which are already installed in several hospitals in Britain. The electrons, bunched together into small clusters and travelling in a hollow 'corrugated' wave-guide, are accelerated by a radio-frequency field which is produced by the propagation of radio-frequency power of short wave-length (usually 10 cm.) along the wave-guide. The design of the wave-guide is such that the velocity of propagation of the radio-frequency field matches that of the accelerating electrons, so maintaining the phase relationship between field and beam and ensuring the continuous acceleration of the electrons along the whole length of the wave-guide. A radio-frequency feedback system is used to increase the energy of the beam, which is released in pulses of 2 μsec. duration at a rate of between 50 and 500 pulses per sec. The power of the beam is of the order of 500 watts, corresponding to a mean beam current of 125 μamp. At the output end of the accelerator an alternating field fans out the electrons so that they scan an area of 12 in. × ¾ in. as they emerge from an aluminium foil window.

The construction of the laboratory itself leaves nothing to chance in the matter of safety. A system of interlocked doors ensures that access to the treatment room (surrounded by massive concrete walls with 4-in. steel plates at strategic locations) or to the accelerator room automatically renders the apparatus harmless. All the control equipment is centralized and is well clear of any radiation or high-voltage hazard. Articles to be irradiated may be mounted either on a variable-speed continuous conveyor belt or a specially designed work-table, both of which are operated by remote control.

The property which makes irradiation a useful process is the disruption which it causes, particularly in large molecules. When biological systems are irradiated, three types of change may occur. Slight irradiation will lead to no obvious damage to the organism, but through the agency of gene mutation may promote the evolution of new genetic types. This offers the interesting possibility that, by exposing quantities of seed to radiation, the probability of producing mutations and of occasionally finding some improved plant strain may be greatly increased. Greater doses of radiation may render sterile the irradiated organism. A suggested application of this property is the improvement of the storage properties of some vegetables, such as potatoes, by preventing them from sprouting.

However, the most fascinating possibilities seem to arise from the utilization of the lethal effects of very large doses of radiation as a bacteriocide. Foodstuffs which normally deteriorate through bacterial infection have their keeping properties much improved by irradiation; unfortunately, the dosage required to exterminate the bacteria sometimes renders the food unpalatable, a difficulty which has still to be overcome. An even more attractive application is in the sterilization of certain types of pharmaceutical products; due to chemical instability or unfavourable physical properties, it may not be possible to use the usual high-temperature methods of sterilization, and irradiation may be used with a temperature rise of a few degrees only. In addition, the product may often be treated in its finally packaged state, ready for distribution.

The irradiation of polymeric substances frequently results in useful changes of their properties. These changes may be roughly classified into two types. In the first of these C—H bonds are ruptured to give a hydrogen atom and a free polymer radical. Two radicals combine to give a larger molecule, a process known as cross-linking, and a molecule of hydrogen is liberated. If the irradiation dosage is large, so many cross-linkages may be formed that the whole specimen becomes virtually a single huge molecule which is extremely inert chemically and insoluble in most solvents. The other type of change which may occur is known as degradation. The polymer is broken down into simpler hydrocarbons, some of which are gaseous and held in the substance under high pressure. Subsequent heating of the polymer softens it and allows this gas to expand, thus producing a foamed material the low density and other characteristic properties of which have found useful applications.

The new laboratory has been set up by Metropolitan-Vickers to provide an irradiation service for other industrial firms and organizations. In doing so the Company has demonstrated a degree of initiative which one hopes will be matched by its potential customers. It is pleasant to witness an industrial enterprise which is not content merely to keep abreast of current scientific advance but which also itself makes a noteworthy contribution to scientific progress.

THE PROGRESS OF WORLD HEALTH

On April 7 the World Health Organization marked its tenth anniversary by sponsoring the celebration, on that date, of a World Health Day in London. As its director-general, Dr. M. G. Candau, said, there have been, during the past ten years, great scientific advances—new drugs, new vaccines, new and better insecticides, more effective methods of fighting or preventing disease. Governments have learnt to take responsibility for the health of their peoples and to provide not only hospitals and health institutions, but also better food and better care for mothers and the young; and eighty-eight countries are now members of the World Health Organization.

How much has been achieved was outlined by Dr. H. van Zile Hyde, chief of the United States Division of International Health. Infectious disease has handicapped man throughout his history. History has, in fact, often been changed by diseases such as typhus, influenza, plague and malaria. But in limited areas of the world in which it has been possible to apply the knowledge acquired by medical science, the epidemics of the past—cholera, smallpox, plague and yellow fever—are no longer feared. Malaria, prevalent in regions in which three-fourths of mankind live, has been conquered to such an extent that whereas, in 1948, 300 million people had malaria each year and 3 million died of it, these figures have to-day been cut by 30 per cent. This disease is still one of the most formidable menaces, but its eradication, already achieved in certain areas, is now possible almost everywhere in the world. It is likely that it will, in a few years, be controlled in the United States, and no new infections with it are expected in the U.S.S.R. after 1960. In the eastern Mediterranean, a traditional reservoir of the disease, great progress in its control has been made. The most serious problem is presented by Africa south of the Sahara, but here also much has been achieved.

The list of other scourges controlled is long and encouraging. Respiratory diseases, such as pneumonia, the common cold and influenza, still flourish; but whooping cough, though it still resists, is in retreat. The international spread of epidemic diseases, formerly controlled by quarantine regulations which imposed great hardships and delays in travel and commerce, is now reduced, in spite of increased possibilities of spread of these diseases by the aeroplane, to the relatively easy conditions of the International Sanitary Regulations designed by the World Health Organization and adopted in 1951.

Many diseases formerly feared, such as cholera, typhus, smallpox, yellow fever, tuberculosis, and those menaces of childhood, scarlet fever, measles and diphtheria, are now virtually under control and, if they occur and are properly handled, they rarely kill. The decline of mortality is, in fact, one of the most significant features of the health record of the world, but it creates new problems that are serious. More elderly people must be fed and housed and given work; the diseases of later life, such as cancer, diabetes and heart disease, are commoner. The stress of modern life is also taking its toll, and great quantities of drugs are manufactured to counter this stress. Whereas infectious and parasitic diseases have been reduced by half, accidents, especially among the young, are leading causes of death. For the very young, on the other hand, and for the mothers who bear them, there is much greater chance of health and happy life.

Thus people born nowadays may expect, apart from accidents, a safer, longer and happier life than earlier generations could. They owe this, of course, primarily to the work of men and women of all nations who have provided the knowledge on which this remarkable progress has been based, and also to the work of the World Health Organization and kindred organizations which have integrated and correlated the work done by individuals and teams in various parts of the world. A major problem of the future would seem to be the diseases of later life, such as cancer, diabetes and arteriosclerosis. If so much has been done in a decade, there is every hope that these diseases also will soon be added to the list of scourges that man has overcome.

EAST AFRICAN VIRUS RESEARCH INSTITUTE

THE annual report* of the East African Virus Research Institute, Entebbe, for 1956–57, which includes a list of papers published during the year and a list of scientific and technical staff as at June 30, 1957, records that the mechanism of transmission and maintenance in Nature of the arthropod-borne viruses continue to be the main interest of the Institute. A systematic programme was commenced to identify the viruses concerned in the causation of fever in man in Uganda. Rabies were recorded in the Entebbe area for the first time and the Institute was largely responsible for identifying the agent. Studies on *Arvicanthis abyssinicus*, a common rodent in Uganda, indicated that it may be important as a host in maintaining Rift Valley fever virus in Nature. Two strains of Zika virus were isolated from *Aedes africanus* mosquitoes collected in forest near Entebbe.

Much attention continued to be given to yellow fever. Some modifications were made in yellow fever neutralization test methods. A more detailed analysis of the sera collected in Northern Rhodesia in 1950–52 indicates that in the four districts mainly involved both sexes are exposed to infection, but rates are generally higher in males than in females; in males infection-rates generally increase with age. In several tribes or localities this is true of females only up to about twenty-four years of age. Twenty-five monkey sera from Tanganyika were all non-immune, but five immune individuals were found among thirteen Brazza's monkeys (*Cercopithecus neglectus*), and laboratory studies indicated that this monkey was likely to be an efficient host for yellow fever virus in Nature. No antibody could be detected in the study of the hæmagglutination inhibition antibody reaction of a bush-baby (*Galago crassicaudatus*) on infection with yellow fever virus.

In the entomological field most attention has been devoted to mosquitoes, especially *Aedes* (*Stegomyia*) spp. The intermittent trap for sampling insects attracted to live bait continued to give encouraging results. Studies are reported of the oviposition cycle in *Aedes aegypti*, *A. africanus* and *Taeniorhynchus fuscopennatus* and of the hormonal mechanisms involved in the reproductive cycle of mosquitoes. Extensive studies of *Aedes aegypti* both in Entebbe and on the Kenya coast, to determine whether the population of this species is made up of 'races' differing biologically, indicate that man is an important host both in Uganda and on the Kenya coast. The hosts of some other mosquitoes have been determined: *A. simpsoni* feeds mainly on man; *Taeniorhynchus fuscopennatus* feeds mainly on mammals and the other *Taeniorhynchus* spp. attack mainly birds.

ARIZONA METEORITE CRATER

DURING the summer of 1956 the Smithsonian Astrophysical Observatory sent an expedition to investigate the distribution of pieces of meteoritic material that are scattered through the mantle of soil surrounding the Arizona Meteorite Crater, the object being to determine more accurately the mass of the meteorite that made the crater and also the direction of its flight. J. S. Rinehart has now published the results of this survey (*Smithsonian Contributions to Astrophysics*, 2, No. 7: "Distribution of Meteoritic Debris about the Arizona Meteorite Crater". Pp. ii+145–160. Washington, D.C.: Government Printing Office, 1958. 20 cents). Niniger had previously worked on the same subject and had published his results in 1956 with his method for extracting the meteoritic material from the soil surrounding the crater, but Rinehart's method was different. He developed a special magnetic separator consisting basically of a vibrating hopper and a slanted trough down which the soil moves under the combined action of gravity and vibration. Above the trough were suspended three strong 'Alnico' magnets to which the magnetic material flies up and adheres as the soil moves downwards. Many precautions were necessary to secure reliable results and these are described very fully.

Estimates of the total mass of finely divided meteoritic material around the crater suggested that this is about 12,000 tons, but this figure is subject to some uncertainty. It is believed that about one-fourth of this mass may be terrestrial oxygen that combined with the meteoric iron after its encounter with the Earth. In addition, there does not appear to be any way for ascertaining accurately the amount of contaminating material present. After taking into consideration a number of uncertain factors, it is believed that the computed mass of 12,000 tons may have to be reduced by about 10–20 per cent.

It is suggested that the meteorite approached the Earth from a south-westerly direction, and after the collision threw forward large quantities of meteoritic material to the position where it now rests. As no piece more massive than 2,000 lb. has ever been found, while thousands of pieces weighing a few ounces or less have been recovered, it is believed that the meteorite was shattered into fragments when it struck the Earth, melting and evaporation accompanying this disintegration. The results so far provide no indication as to whether a large mass of meteoritic material lies buried in the crater. If we accept the low estimates of 10,000–15,000 tons for the mass needed to form the crater, then no large mass could remain in the crater. If, on the other hand, the estimates of Öpik and of Rostoker are nearer the true value, then the amount of meteoritic debris so far recovered is insignificant, and a large mass may be buried underneath. Dr. F. L. Whipple, in a personal communication to the author, expresses the view that a most reasonable mass is that given recently by Hill and Gilvarry, namely, between 80,000 and 400,000 tons.

MEANING OF DENSITY-DEPENDENCE AND RELATED TERMS IN POPULATION DYNAMICS

ONE of the most familiar concepts of population dynamics is the idea of the regulation of abundance by density-dependent factors, which operate more severely at high density than at low density, per individual of a population. But there has been some variation in the meaning and scope of 'density-dependent' and related terms as used by different authors, and in recent years this tendency has increased. This has led to some confusion, and poses the question how the application of these terms can be stabilized. Varley[1-3] has argued that the meaning and scope of such a term should be determined strictly according to its author's definition, and that on this basis insect parasites, predators and disease organisms should be excluded from the density-dependent category. Discussion of this matter with Prof. Varley has not altered my opinion that it is too late to attempt to make a change so contrary to the intentions of the originator of this term, and to subsequent common usage, but has led to various improvements in the present article.

In order to deal with a number of points which are closely inter-related, it is proposed : (1) to look back to the origins of the terms concerned, then (2) to give a brief account, similar in some respects to that given by Varley[3], of the variations in the use of these terms by various authors, and of a number of synonyms, and finally (3) to discuss various proposals for clarifying the position.

(1) Howard and Fiske[4], discussing the natural control of insects with special reference to defoliating caterpillars, wrote that for natural control, or balance, to exist "it is necessary that among the factors which work together in restricting the multiplication of the species there shall be at least one, if not more, which is what is here termed facultative . . ., and which, by exerting a restraining influence which is relatively more effective when other conditions favour undue increase, serves to prevent it". The chief of such facultative factors was stated to be parasitism, "which in the majority of instances, though not in all, is truly 'facultative' ".

They considered disease as a type of facultative factor which, in their experience, became effective chiefly at a very high level of abundance, and starvation as operating only at the extreme limit. Generally, insects would be controlled at a low level of density "only through parasites and predators, the numerical increase of which is directly affected by the numerical increase of the insect upon which they prey".

Secondly : "A very large proportion of the controlling agencies, such as the destruction wrought by storm, low or high temperature, or other climatic conditions, is to be classed as catastrophic, since they are wholly independent in their activities upon whether the insect which incidentally suffers is rare or abundant. . . . The average percentage of destruction remains the same. . . ."

Thirdly : "Destruction through certain other agencies, notably by birds and other predators, works in a radically different manner . . . it may be considered that they average to destroy a certain gross number of individuals each year, and . . . this destruction . . . would most probably represent a heavier percentage when that insect was scarce than when it was common. In other words, they work in a manner which is the opposite of 'facultative' as here understood."

In short, Howard and Fiske recognized three types of factors : (*a*) 'catastrophic' ; (*b*) 'facultative' and a third type which was later called (*c*) 'inverse'[5]. Later, Thompson[6] divided controlling factors into two classes. One, which he named 'general', was the same as Howard and Fiske's catastrophic type. The other comprised "those *individualized* factors whose destructive capacity depends in some way on the numerical value of the host population" ; this definition takes in two of Howard and Fiske's categories, the facultative and the inverse factors ; it is clear from this paper and from Thompson's later writings[7] that he means chiefly parasites, but he considers that, because of their limited reproductive capacities, they generally act as inverse factors.

It was H. S. Smith[8] who introduced the new terms 'density-independent' and 'density-dependent' for Howard and Fiske's catastrophic and facultative categories. He made the mistake of identifying the facultative or density-dependent class with Thompson's individualized category ; but his designation, "destroying a percentage which increased when the numbers of the host increased", shows that he did not mean to include inverse factors ; indeed, he followed Howard and Fiske in recognizing them as a distinct third category, again citing "many insectivorous birds and mammals" as examples. His examples of density-independent agents included climatic factors, 'intrinsic' mortality, and malnutrition due to unsuitable food. Examples of density-dependent factors were, primarily, entomophagous insects, then certain infectious and contagious diseases, quantity of food and competition for nesting sites or protective niches ; the last-mentioned process, it was suggested, was a medium through which climatic factors could have a density-dependent action.

Thus Smith and Howard and Fiske agreed in designating facultative or density-dependent factors as those having a greater proportionate influence at high than at low population density, and also in regarding insect parasites, or entomophagous insects (Smith), certain pathogens, and food shortage as examples ; Smith added intra-specific competition, and hence (in his view) certain climatic factors. Varley[1-3] has insisted that the definition and the examples are at variance, inasmuch as theoretically constructed parasite-host oscillations show a relationship which, owing to the delayed response of parasite numbers to changes in host numbers, is alternately density-dependent and inverse. It may be added that interactions broadly similar to the theoretical ones have been demonstrated in laboratory experiments and in a fragmentary form in certain field populations, though not in others. Nevertheless, the great majority of writers on the subject have accepted Smith's ideas and terms, presented as they were without formal definition, and have been content to use them in a not too precise way; in particular, most writers have accepted all those insect parasites and predators exerting a regulating influence upon a population as density-dependent factors; whether or not their response to host density might be so delayed as to prevent any consistent and straightforward density-dependence has been little considered.

(2) There have, however, been a number of variations in the application of Smith's terms, and various new terms have been used by authors wishing to avoid confusion. The term 'density-independent' has suffered relatively little misuse. But in his text-book, Odum[9] refers to a type of inverse factor as density-independent, and uses a new term, 'density-proportional', for one type of density-independent factor.

With respect to the term 'density-dependent', a major source of confusion is that some authors have taken it to include inverse factors, which Smith specifically excluded. Allee[10] and Allee *et al.*[11] did this, and then separated 'direct density-dependent' from 'inverse density-dependent' factors. Haldane[12] did likewise, but called these two subdivisions 'negative' and 'positive density-dependent'. Thompson[7] writes that Smith proposed the new term 'density-dependent' for Thompson's individualized category. This, as already noted, was an error on the part of Smith[8]; for, like Howard and Fiske[4], he explicitly separated the inverse type of factor into a separate category.

Milne[13] makes a distinction between 'perfectly' and 'imperfectly' density-dependent factors: "Perfection here means an *exact* linear (or curvilinear) relationship between increasing action of the factor and increasing density of the species". The only perfectly density-dependent factor is said to be competition between members of the population. I do not believe that factors perfectly dependent on density exist except at a high level of abstraction. In Nature, the actions of all factors are presumably variable and inexact.

Varley[1,2], in separating parasites, predators and pathogens from the density-dependent category, called them 'delayed density dependent' factors. Lack[14] has treated this new category as a subdivision of the density-dependent class.

Some synonyms of density-dependent are 'facultative'[4], 'controlling'[15], 'concurrent'[5] and 'density-governing'[16].

'Inverse' factors of various types have been called 'density-disturbing'[16], 'inverse density-dependent'[10,11], and 'positive density-dependent'[12]. Odum[9] refers to one sort of inverse action as an inverse type of density-dependence, and to another sort as density-independent. The terms positive or inverse density-dependent, as we have seen, extend the density-dependent category beyond the limits laid down by its originator.

There is, of course, an important characteristic held in common by density-dependent and inverse factors: the action of both is related to population density, though in opposite senses. Terms (other than density-dependent) which have been used for including both these types of factors together are 'individualized'[6], 'density-related'[5] and 'reactive'[16].

(3) Turning now to the question how to standardize the use of the term density-dependent and reduce the confusion which has beset it in the past, there are three main possibilities:

(*a*) The first is to follow the course advocated by Varley[2,3], and place a strict interpretation on the explanations (scarcely formal definitions) given by Howard and Fiske[4] and by Smith[8]. What the result of this would be depends upon whether or not many insect parasites and predators do in fact maintain an oscillatory relationship, of the type seen in mathematical theories, with the populations of their hosts or prey. If Varley's[2] expectations are correct, parasites and predators would generally be excluded from the density-dependent category of which Smith took them to be the prime exemplars. Besides running counter to the intentions of the originator of the term, this would give density-dependence a far narrower meaning than it has been given throughout the extensive literature in which it has been used over the past two decades. (The only exceptions to this, so far as I am aware, are papers by Varley[1-3].) I believe such a restriction of the scope of this familiar term would be unlikely to find general acceptance, and that after such a long period it would cause a great deal of further confusion if it were adopted.

(*b*) The second possibility is to follow the example of Allee[10], Allee *et al.*[11], and Thompson[7], and take the density-dependent category to include, not only all the types of factors attributed to it by Smith, but also the inverse factors, which he excluded. In support of this course, it may be said that it has been fairly widely favoured, and that it interprets density-dependent in the literal sense of "acting in a way which is dependent on density". But I doubt whether it accords with a majority viewpoint, and am opposed to it because it gives the term density-dependent a quite different scope from that laid down by its originator.

(*c*) The third possibility is to follow the intentions of Smith as closely as possible, by including, along with intraspecific competition and other straightforward density-dependent factors, those parasites, predators and pathogens which respond to changes in host population density in such a way as tends to limit these changes (even if the response is delayed as in the theoretical parasite/host oscillations), and by excluding only those factors the action of which wholly or predominantly maintains an inverse relationship with density, and those which are independent of density. Many writers have explicitly or implicitly adopted a similar interpretation. I suggest that, in so far as the term 'density-dependent' continues in use, this is the way in which it should properly be applied.

Whichever course is followed, one major difficulty is inescapable for the present: there are very few ecological situations which are well enough known for particular biological factors to be placed with confidence in any one of Smith's three categories. Still less can we say in general what proportion of insect parasites and predators act as density-dependent, or inverse, or density-independent factors.

The writer on this subject may often prefer to avoid using the term 'density-dependent'. One alternative is to use Nicholson's term 'density-governing'. Nicholson[16] writes that "its meaning is precisely that of 'density-dependent factor' according to definition (Smith, 1935)", and, like Smith, he puts inverse factors in a separate category (density-disturbing). A possible objection to the term 'density-governing' is the implication that all density-dependent factors have a governing influence upon density, which seems unlikely.

As a means of avoiding the various difficulties associated with the use of 'density-dependent', and at the same time recognizing the special features of the factors Varley[1] called 'delayed density dependent', the following classification may be useful. It sets out some types of relation which the unfavourable action of factors upon a population may bear to the density of that population, the action being measured as an effect upon mortality, the reproductive rate, or the net rate of increase or decrease, and expressed in proportionate terms such as percentage.

(1) 'Directly density-related': showing a positive correlation between adverse action and density.

(2) 'Inversely density-related' (or 'inverse'): showing a negative correlation between adverse action and density.

(3) 'Alternately density-related' (or 'alternating'): where a lagging response to changes in density leads to a regular succession of directly and inversely related phases.

This last category is distinguished from the density-independent (or non-reactive[16]) relationship, where the correlation between action and density would generally vary (in successive short runs of observations) in an irregular manner between positive, zero and negative, with a long-run correlation not differing significantly from zero.

A single factor might fall in different categories in different circumstances, or at different levels of abundance or (as pointed out to me by Dr. R. F. Morris, of Canada) within a single generation as compared with a series of generations.

Upon such questions as what sort of ecological causes may lie behind the correlations observed, which factors may be found to fall in which category under various conditions, and what may be their function in natural control, this classification is deliberately left non-committal.

MR. SOLOMON directs attention to a serious state of affairs which is making the study of population dynamics unnecessarily confusing. While agreeing with his analysis of the past use and misuse of the terms, I think that the reasons for the confusion require closer study, and I also disagree with his recommendations. This disagreement involves the principles on which scientific terminology should be based, and it would be interesting to have the views of workers in other fields of science, where there are comparable difficulties.

Here the issue in question concerns the way in which animal populations are stabilized, and there are at least two quite different models which may be used for explaining such stability, and mortality relationships appropriate to each require different terms if confusion is to be avoided. The first and simplest is that of Verhulst, Pearl and others which considers one species only, and assumes that its relative rate of increase is reduced by rising population density. There is a single population density at which the rate of increase is zero. Whether the population density is initially above or below this it will rapidly approach this equilibrium position. In my opinion a mortality factor which stabilizes a population in this way fits best with Smith's term 'density-dependent'.

The second model is more complex and concerns the interaction between two species, predator and prey, or parasite and host. It has been studied mathematically by Lotka, Volterra and in a special form by Nicholson and Bailey. On this model populations show oscillations, and mortality in the prey or host species does not show a simple relationship to its own population density. Actually, the maximum mortality lags a quarter of a cycle behind the population density. Hence my term 'delayed density-dependent factor' (Varley, 1947). Similarly, the maximum rate of increase of the predator or parasite is a quarter of a cycle after its own population minimum, so that the effect is delayed, being density-dependent for two quarters of the cycle, and inverse for the other two.

From the beginning there has been confusion between these two models. Howard and Fiske's explanation (*l.c.*, p. 107) of their term facultative has been quoted in part by Solomon, but the phrase "when other conditions favour undue increase" is vague; they also say (p. 108) that facultative agencies "effect the destruction of a greater proportionate number of individuals as the insect in question increases in abundance", which is consistent with model one. They did not seem to appreciate that model two was basically different. They realized that parasites and predators had a regulatory influence on populations, and cited them as examples to which their term applied. There is, however, no evidence from studies of parasite behaviour to warrant this citation.

Nicholson (1933) likewise seems to confuse the models. Having given examples of balance of populations of *Tribolium*, etc., *in vitro*, he says (*l.c.*, p. 135) that "for the production of population balance, it is essential that the controlling factor should act more severely against an average individual when the population density is high, and less severely when the population is low". Such a controlling factor clearly agrees only with model one, and the examples he had just considered have often been fitted by the Verhulst–Pearl equation. Nicholson then proceeds to elaborate his theory of population balance by parasites, which is a form of model two. He does not point out that according to his theory the host's mortality due to parasitism reaches its maximum not when host density is maximal, but when it is half-way down to its minimum again. Hence parasites, according to his theory, do not fit his definition of controlling factors which I have quoted. Nor does Nicholson seem to recognize the distinctive nature of model two even in his 1954 paper.

A second cause of confusion, as rightly pointed out by Mr. Solomon, is that certain workers have interpreted the term 'density-dependent' literally, and divorced it from its original restricted definition. This I consider to be deplorable, and contrary to general scientific practice. Thus biologists do not apply the term 'chromosome' to any coloured body.

Thirdly, as seen from Solomon's review, various workers have re-defined and used the term 'density-dependent' in different or even in opposite senses from that originally defined. This raises the question whether scientists should adopt rules for the purpose of conserving the meaning of terms.

Mr. Solomon considers three ways of treating Smith's term 'density-dependent', and favours the last, (*c*), which is to sanction the application of the term to parasites and predators. This puts more weight on Smith's examples than on the definition or explanation of Howard and Fiske to which Smith referred. Further, this course probably involves the rejection of the original definition of the term, and therefore the provision of a new definition. Since Thompson and Nicholson have entirely different ideas about the ways in which parasites react to host population changes, and observations are as yet inadequate to give a clear decision[1], an agreed definition cannot be given at the present time if parasites are to be an example of the term's correct application. Is it not wiser for the present to refer to these animals simply as parasites or predators, and avoid being committed to any particular hypothesis concerning their influence on populations ?

The second solution (*b*) which Solomon rejects would also require a formal change in the definition of the term 'density-dependent'. Although various authors have used the term in senses different from that originally defined, I agree with Solomon that there seems to be no valid reason for following any of them. The consequences of permitting scientific terms to be altered in such a way are serious.

I am convinced that the best course, though Solomon rejects it, is to accept a precise definition of 'density-dependent' in accordance with model one, which I believe to be what the original authors had in mind, and it is in this sense that I have interpreted the term in the papers cited. This, it is true, means that parasites and predators are excluded as examples, but as already stressed, their action probably conforms more to model two. While Solomon claims that to narrow the scope of the term in this way is confusing, I think that distinctive terms are required for mortality relationships in the two models, and that this will help to clarify the issues involved.

Possibly there is a case for rejecting all these old terms simply on the grounds that they have been perverted and inverted by various authors ; but on balance I prefer to use them and to retain their original definitions. I can see little advantage in adopting Solomon's three new terms, although they provide a good logical system, since they are synonyms of terms already in use. If these new terms come to be misused in the future, must they be cast aside in turn ?

I am grateful to Dr. D. Lack for discussing a draft of this reply, and helping to remove some ambiguities.

BITING BEHAVIOUR OF MATED AND UNMATED FEMALES OF AN AFRICAN STRAIN OF *AEDES AEGYPTI*

By M. M. J. LAVOIPIERRE

Department of Entomology and Parasitology, Liverpool School of Tropical Medicine

IN the course of extensive studies on the biting behaviour of an African strain of *Aedes aegypti*, which has been maintained in the Liverpool School of Tropical Medicine since 1938, it was observed that the mated and unmated females behaved differently. Gillett[1-3] has studied the development of the oocytes and the oviposition habits of several African strains of the same species of mosquito and has provided evidence for the presence of an ovarian development hormone and suggested the existence of an ovulation hormone, the production of which appears to be usually dependent on previous mating. While the investigations being undertaken in Liverpool are not directly concerned with a study of these hormones, the experiments described in this preliminary communication may throw some further light on the hormonal control of gonadotrophic activity in the mosquito.

In each of the experiments in which the biting behaviour of fertilized and unfertilized mosquitoes was compared, the adult insects were obtained from the same 'crop' of pupæ so that both populations were exactly comparable. The mosquitoes were kept in organdy cages in an insectary, the temperature of which varied between 75° and 85° F. and the relative humidity between 70 and 82 per cent ; illumination was provided only during the day, by means of neon lamps. Feeding on a sensitized human volunteer was begun on the second day after emergence when a high proportion of the mosquitoes were likely to feed[4], and the flies were afterwards offered a meal on the same volunteer for exactly 5 min. daily.

The results of the experiments, which were carried out in the summer of 1957, showed that the numbers of fertilized mosquitoes which fed decreased markedly in the first few days, the lowest level of feeding corresponding with the onset of the oviposition-cycle. Feeding in the fertilized mosquitoes then showed a cyclical pattern with the intervals corresponding to those of the oviposition-cycle. On the other hand, in the case of the unfertilized mosquitoes, biting was maintained at a high level from the onset of feeding, while the egg output was very low ; in its oviposition habits the Liverpool strain of *A. aegypti* appears to behave similarly to the Newala strain described by Gillett[1]. There was a slight variation in the various experiments carried out, but the basic pattern as illustrated in Fig. 1 was repeated, particularly in the

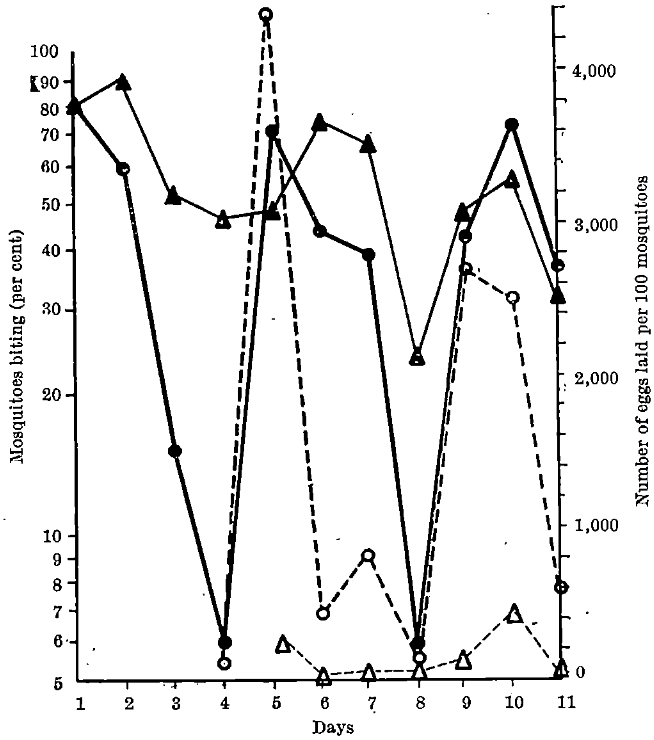

Fig. 1. Graph showing the relationship between the biting and oviposition curves of a group of 52 fertilized *Aedes aegypti* and the relationship between the biting and oviposition curves of a comparable group of 52 unfertilized *A. aegypti*. The biting curves are plotted on semi-logarithmic co-ordinates and the oviposition curves are plotted on arithmetical co-ordinates. The experiments were started on July 2
●, Fertilized biting curve; ▲, unfertilized biting curve; ○, fertilized oviposition curve; △, unfertilized oviposition curve

first few weeks of each experiment. As the populations aged the picture was not quite so clear cut, due to a number of complicating factors, the nature of which will be discussed when a full account of these results is published.

Dissections of a control group of fertilized mosquitoes belonging to the experiment illustrated in Fig. 1 showed that biting fell off sharply after the oocytes had reached the third stage, and that mosquitoes which fed at the late third or fourth stage of oocyte development generally took smaller meals than mosquitoes with oocytes of an earlier age. In a group of 55 fertilized mosquitoes, only 2 out of 23 flies which had fifth-stage oocytes had taken a blood meal and both presented abnormal features; in one individual only the right ovary contained fifth-stage oocytes, while in the other mosquito each ovary contained only a few fifth-stage oocytes. On the other hand, dissections of a comparable control group of unfertilized mosquitoes, carried out on the fifth day, revealed that all the mosquitoes possessed oocytes at the fifth stage of development although biting was proceeding at a high level. These results are of great interest when compared with those of field workers such as Teesdale[5] and Macdonald[6].

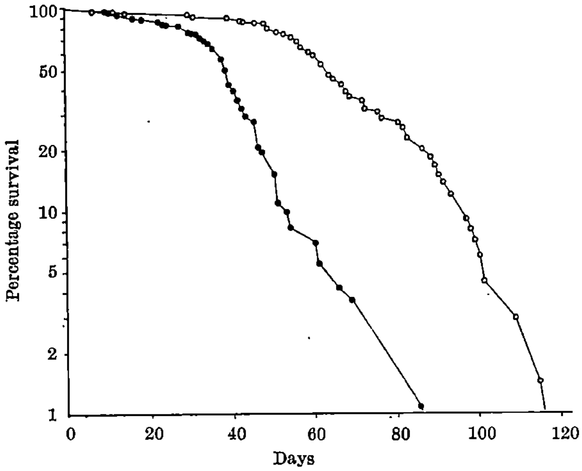

Fig. 2. Survival curves for comparable groups of fertilized ○ and unfertilized ● *Aedes aegypti* which had been offered a blood meal daily, plotted on semi-logarithmic co-ordinates

The explanation of the sharp reduction in the biting activity of the fertilized females, as the oocytes developed, is not clear. It is certainly not due to a pressure effect, since unfertilized females with retained and pigmented eggs, and with an extensive fat body, readily took up blood. It therefore appears probable that avidity for blood is under hormonal control and closely associated with events in the gonadotrophic cycle of the ovipositing mosquito. While it is manifestly dangerous at the present stage of our knowledge to speculate too freely about the mechanisms controlling cyclical feeding, it is tempting to suggest that the production of increasing amounts of ovulation hormone in the gravid fertilized mosquito inhibits the mechanisms by which the mosquito is induced to feed and that this inhibitory effect is very rapidly removed following oviposition. Whatever the final answer to the problem, it probably will not prove to have a simple solution.

Studies on the survival of fertilized and unfertilized populations of *Aedes aegypti* which were offered a blood meal daily showed that the rate of death of unfertilized females was greatly increased when compared to that of fertilized females (Fig. 2). That the increased rate of death of the unfertilized females was not due directly to the effect of feeding but to some factor or factors associated with the retention of the ova was shown by the fact that two curves plotted for unfertilized populations, one of which was offered a blood meal daily and the other every 10 days, coincided almost exactly.

Finally, it should be noted that the term 'biting cycle' is used in this context to describe the type of cyclical biting activity shown in Fig. 1 in accordance with Kleitman's[7] nomenclature. This is not to be confused with the nycthemeral biting curve which is usually referred to as the 'biting cycle' and which appears to be controlled by factors other than those discussed in this paper. While it may be necessary in the future to reconsider carefully the nomenclature of cyclic, rhythmic and periodic phenomena in mosquito biology, it is my feeling that this can only be done profitably when more is known about the mechanisms which control the vital activities of the insect.

DEVELOPMENT OF LYSOZYME-RESISTANCE IN *MICROCOCCUS LYSODIEKTICUS* AND ITS ASSOCIATION WITH AN INCREASED O-ACETYL CONTENT OF THE CELL WALL

By Dr. W. BRUMFITT and Dr. A. C. WARDLAW
Wright-Fleming Institute, St. Mary's Hospital, London, W.2

AND

Dr J. T. PARK*
Medical Research Council Unit for Chemical Microbiology, Department of Biochemistry, University of Cambridge

FROM a typical lysozyme-sensitive strain of *Micrococcus lysodiekticus*, resistant variants have been obtained by serial subculture on nutrient agar containing increasing amounts of lysozyme[1]. The most resistant of these variants, strain 250, grows on nutrient agar containing 4,000 μgm./ml. lysozyme, whereas the parent strain *L2* (N.C.T.C. 2665) fails to grow on nutrient agar containing 0·1 μgm./ml. of the enzyme. Cell walls prepared from the two strains show marked differences in their sensitivity to lysozyme action as measured either turbidimetrically or by release of N-acetyl hexosamine[2] as shown in Table 1. In this experiment the cells of strain 250 from which the walls were obtained were grown on nutrient agar containing 1 μgm./ml. lysozyme to inhibit the growth of sensitive variants.

Various explanations for the lysozyme-resistance of strain 250 have been sought[1], but particular attention has been given to the possibility of a chemical alteration in the cell wall, since this structure contains the substrate of lysozyme[3]. Analysis of the cell walls of strains *L2* and 250 revealed no major differences in their sugar or amino-acid composition[1]. However, when O-acyl estimations were made by the method of Hestrin[4], a marked difference between the two strains was revealed. The results in Table 1 show that the cell walls of the resistant strain contained more than one-hundred-fold greater content of O-acyl groups than the cell walls of the sensitive strain. Similar differences were also observed with whole cells. Paper chromatography[5,6] has identified the acyl groups as being principally acetyl.

These observations suggested that the lysozyme-resistance of strain 250 might be due to the ability of this organism to acetylate certain cell wall hydroxyl groups, associated with the lysozyme substrate, which in the sensitive strain are free. On the basis of this hypothesis, we have explored the possibility of using chemical procedures to alter artificially the lysozyme-sensitivity of *M. lysodiekticus* cell walls by changing their O-acyl content. Thus we have tried to make the resistant cell walls sensitive again by removing the O-acetyl groups with sodium hydroxide and, conversely, to render the cell walls of the sensitive strain resistant by acetylation with acetic anhydride and pyridine. That these experiments were successful is shown in Table 1.

Table 1. Comparison of O-Acyl Content and Lysozyme-Sensitivity of the Cell Walls of Sensitive (*L2*) and Resistant (250) Strains of *M. lysodiekticus*, and the Effect of Previous Treatment of Cell Walls with (*a*) Sodium Hydroxide, (*b*) Acetic Anhydride and Pyridine

Strain	Treatment	O-Acyl content of cell wall (μM/gm.)	Lysozyme sensitivity*	
			Percentage reduction in O.D.	Glucosamine released (mgm. per cent cell wall)
			After 90 min. at 37°	
L2	None	3	68	3·1
250	None	433	15	0·4
250	NaOH	5	62	2·2
L2	Ac_2O/pyr.†	305	26	0·8

* In lysis tests the lysozyme concentration was 1 μgm./ml. while in estimations of glucosamine release 10 μgm./ml. was used. O.D. estimations were made on the Spekker, using grey filters.

† 80 mgm. cell walls + 20 ml. acetic anhydride + 1 ml. pyridine, 1 hr. at 37°, followed by washing at 0° in *p*H 7 phosphate buffer, first 0·2 *M* (twice), then 0·01 *M* (thrice).

Armour Laboratory crystalline egg-white lysozyme was used throughout this work.

By milder treatment it was possible to make the intact cells of strain 250 sensitive to lysozyme, but without the loss of viability that accompanied treatment with 0·01 *N* sodium hydroxide. For this purpose the cells were incubated 1 hr. at 37° in 0·1 *M* Sørensen phosphate or glycine buffers over the range *p*H 7·0–11·4, after which they were washed repeatedly in 0·01 *M* phosphate buffer *p*H 7·0 at 0°. It was found that although no significant loss of viability occurred up to *p*H 11·4, there was a progressive decrease in O-acetyl content and a corresponding increase in lysozyme sensitivity with increasing *p*H (Table 2). This increased sensitivity to lysis was associated with increased release of N-acetyl glucosamine, which is regarded as a reliable index of breakdown of lysozyme substrate[1]. Subculture of the cells rendered sensitive to lysozyme by treatment at *p*H 11·4 produced colonies the cells of which were once more lysozyme-resistant. It is therefore concluded that strain 250 differed genotypically from strain *L2* in its ability to acetylate cell wall hydroxyl groups. That at least some of these groups are located on the bacterial surface is suggested by the ease with which they can be removed without affecting cell viability. Thus in addition to natural selection, simple chemical treatment can be used to alter the susceptibility of *M. lysodiekticus* to lysozyme, except that the chemically induced changes are not transmitted.

Table 2. Exposure of a Lysozyme-resistant Strain of *M. lysodiekticus* to Alkaline Buffers: Effect on Lysozyme-sensitivity and O-Acyl Content of the Intact Cells

Treatment (*p*H)	Reduction in O-acyl content of cells (per cent)	Lysozyme sensitivity (per cent reduction in O.D.)*
7·0	0	30
8·4	8	37
9·2	11	43
10·3	31	53
11·4	39	75

* Concentration of lysozyme was 2 μgm./ml.

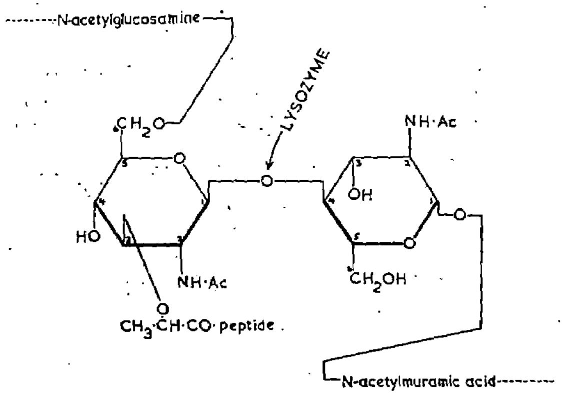

Fig. 1

These findings have led us to speculate on the possible locus of the O-acetyl groups in the cell wall and also on the nature of the bond split by lysozyme. Cell walls of Gram-positive bacteria have a remarkably similar chemical composition[7–9], being composed of three or four amino-acids and two amino-sugars: N-acetyl glucosamine and N-acetyl muramic acid. However, some of these bacteria are sensitive to lysozyme and others completely resistant. When lysozyme acts on susceptible cell walls only a few bonds in the substrate polymer are split, and large molecular weight fragments (10,000–15,000) with N-acetyl hexosamine end-groups are liberated[10]. Based on the results of a differential colour test, it appeared probable that these end-groups are all N-acetyl muramic acid[11] (although if N-acetyl glucosamine were still linked to the polymer through carbon 3, the same colour reaction would be given). The finding that only about 10 per cent of the total N-acetyl muramic acid in susceptible cell walls is made available by the action of lysozyme is in keeping with the size of molecular fragments released.

Disaccharides of N-acetyl muramic acid and N-acetyl glucosamine have been obtained following lysozyme action[10] and acid hydrolysis[12]. It is probable that this disaccharide forms the backbone of the polymer, although beyond this the structure of the mucopolysaccharide attacked by lysozyme is unknown. Assuming for the structure of the cell wall polymer repeating units of the two amino-sugars, let us now consider the possible linkages between them (Fig. 1). The colour yield of the split products in the Elson and Morgan test[13,14] following lysozyme action indicates that carbons 1 and 4 of N-acetyl muramic acid are free. Thus only carbon 6 is available for binding to the rest of the fragment, presumably to carbon 1 of N-acetyl glucosamine. On the other hand, the lysozyme-sensitive bond is probably from carbon 1 of N-acetyl muramic acid to carbons 3, 4 or 6 of N-acetyl glucosamine. It is very likely that lysozyme attacks only one of these bonds, and Berger and Weiser[15] have recently shown that chitin, which is a β 1–4 linked polymer of N-acetyl glucosamine, is slowly split by lysozyme. For this reason we propose the hypothesis that lysozyme splits a 1–4 link between N-acetyl muramic acid and N-acetyl glucosamine.

The effective inhibition of lysozyme by O-acetyl seems to require one acetyl per disaccharide unit. We have found an approximate 1 : 1 molar ratio of O-acetyl to N-acetyl muramic acid in the cell walls of our resistant strain 250. As mentioned earlier, lysozyme does not appear to split readily the bond between adjacent repeating units of the polymer, but acts preferentially on bonds about 10 units apart. From this one would predict that a fully resistant strain would become highly sensitive if only every tenth repeating unit were deacetylated, provided the deacetylated units were properly spaced. The results in Table 2 show that removal of only 40 per cent of the O-acetyl groups from the resistant organism was sufficient to confer high sensitivity to lysozyme. Abrams[16], who first observed the presence of O-acetyl in bacterial cell walls, concluded that these groups were not involved in lysozyme resistance because *Streptococcus faecalis* No. 9190, which contains O-acetyl, is sensitive to the enzyme. We would predict that this organism possesses less than one O-acetyl group per repeating unit and that resistant strains obtained by selection would possess a higher O-acetyl content.

This mechanism of resistance to lysozyme may be of general occurrence in view of the wide distribution of O-acyl in bacterial cell walls (Park, J. T., unpublished observation, and see ref. 16). However, certain cells may use sugars as the blocking agent if one accepts that the essential feature of blocking is the covering of a particular hydroxyl group on the substrate.

Certain cells are essentially resistant to lysozyme possibly because they lack the lysozyme-sensitive bond (1-N-acetyl muramic acid—4-N-acetyl glucosamine). For example, *Staphylococcus aureus* H., which contains a considerable amount of O-acyl, is still resistant to lysozyme after removal of these groups. It is of interest to note that *Staph. aureus* produces a lysozyme-like enzyme, although presumably of different specificity, which enables rapidly growing cells under certain conditions to autodigest their cell walls whereas older cells cannot[17]. It is possible that before new cell wall can be synthesized a preliminary hydrolysis of part of the existing wall, by this enzyme, is necessary. Equally necessary would be a mechanism for protecting cell wall areas remote from this site. Substituents such as O-acetyl groups introduced into the cell wall polymer could clearly fulfil this function.

Various techniques such as those of Nakamura[18] and Repaske[19] are now available for inducing lysozyme sensitivity in a wide range of bacteria which under normal testing conditions are resistant to the enzyme. Whether or not these sensitivity changes are associated with hydrolysis of cell wall O-acyl groups is at present under investigation.

We wish to thank Miss J. A. Gathercole for excellent technical assistance.

BIOLOGICAL EFFECT OF A MAGNETIC FIELD AND THE RADIATION SYNDROME

By M. F. BARNOTHY and J. M. BARNOTHY
College of Pharmacy, University of Illinois

As reported in a previous communication[1], when mice are kept in a homogeneous magnetic field of several thousand gauss, leucocytosis can be observed during the first weeks following the removal of the animals from the field. Both the segmented and the lymphocyte count increase and reach a maximum of 30–60 per cent in 12–14 days after removal of the animal from the magnetic field.

Based on these findings, the following working hypothesis was tested. Irradiation with X- or gamma-rays in the mid-lethal dose-range decreases the granulocyte and lymphocyte count in four or five days, to a few per cent of their normal value[2]. Since this effect of irradiation on the leucocyte count is, in its sign, opposite to that found after removal from the magnetic field, it could be expected that the bone-marrow syndrome in the radiation injury might be partly compensated, if irradiation and treatment in a magnetic field could be adjusted in a proper time sequence.

Eight-week-old virgin *RFM*-strain mice from the Roscoe B. Jackson Memorial Laboratory were used. From the 60 mice used in each experimental series, a sample of 10 or 20 of average weight distribution was selected, and placed for a period of 14 days in a magnetic field of 4,200 gauss. The maximum gradient of the field within the cage was 30 gauss/cm. The remaining mice were kept in standard plastic cages. 'Rockland mouse diet' and tap water were supplied *ad libitum* to both groups. At the end of the 2-week period the treated mice were placed for 2–3 days in standard cages, whereupon to all of them a whole-body irradiation was given in the Cobalt Therapy Unit of Cook County Hospital, at 57 r./min. intensity. All animals were deprived of food 10–12 hr. prior to irradiation to minimize intestinal syndromes[3].

In the following account the radiation dosage is always given for cobalt-60 gamma-rays; in order to convert the dosage to 250 kV. X-ray dosages of the same relative biological effectiveness, the values must be divided[4] by the factor 1·33. The expression 'controls' refers to animals irradiated but not treated in the magnetic field; and the expression 'treated' to animals which were treated in a magnetic field and irradiated.

Table 1 shows the irradiation dosage, the number and age of controls and treated mice at the time of irradiation, the mortality-rates and the probability-level in the difference of the mortality-rates.

In series *C*, the surviving 45 animals of series *B* were used again, and irradiated 44 days after their first irradiation. The same ten animals were treated anew, that is, kept for 14 days in a magnetic field prior to their (second) irradiation.

Table 1

Series	Dose	Age in days	No. of: Controls	Treated	Mortality-rate (per cent) Controls	Treated	Probability-level
A	850 r.	88	41	20	86	75	1:6
A'	850 r.	88	41	10	86	50	1:95
B	750 r.	77	50	10	30	0	1:107
C	850 r.	121	35	10	89	80	1:3·5

As it was shown by one of us, the development of young animals kept in a magnetic field is retarded. After magnetic treatment, the weight of the treated mice averaged 1–2 gm. less than that of their controls. Since, as is known, the irradiation mortality increases with decreasing body-weight, the treated animals were in a somewhat unfavourable situation. In series *A*, 10 of the heaviest mice from the 20 treated were marked. Their average weight was the same as that of the control group. The mortality-rate of this selected group is listed in Table 1 as series *A'*.

The difference in the mortality-rate between controls and treated mice is significant in series *A'* and *B*, but not significant in series *A* and *C*. It is highly significant for the pooled results of series *A*, *B* and *C* as well as for the pooled results of series *A'* and *B*.

In series *A*, blood samples were taken on the 5th, 10th, 15th, 20th and 30th post-irradiation days, from the tail veins of 6 controls and 6 treated. The segmented neutrophile and lymphocyte count dropped on the 5th day in treated and control groups to 3 and 2 per cent, respectively, of the original value. The upper part of Fig. 1 shows the change in the leucocyte count of the treated animals relative to the leucocyte count of the control group. The magnetic treatment does not compensate the leucopænia of the bone-marrow syndrome, but diminishes it by a percentage. Furthermore, it enhances the leucopænia between the 15th and 18th post-irradiation days. In view of these findings, it is not to be expected that magnetic treatment will decrease considerably the mortality-rate of the radiation injury of young mice in the high lethal range.

A significant difference is manifested in the mortality histograms. On the 9th, 10th, 11th and 12th day after irradiation, none of the treated animals

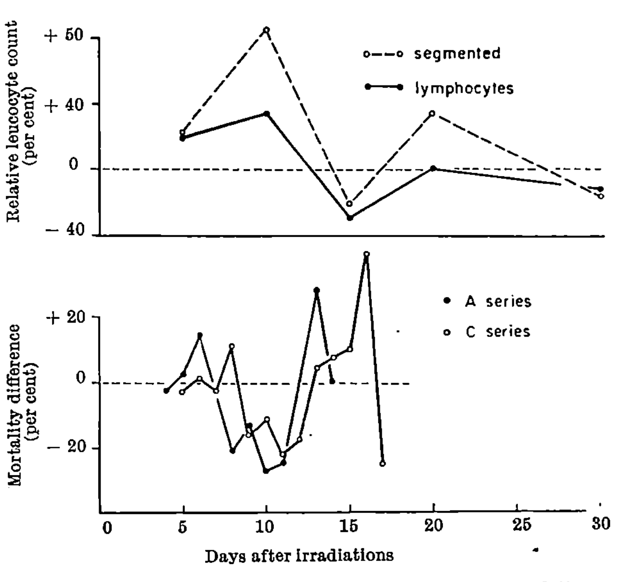

Fig. 1. Upper curves, leucocyte count of treated animals relative to controls; lower curves, mortality of treated above controls as a percentage of preceding-day survivors, for series *A* and *C*

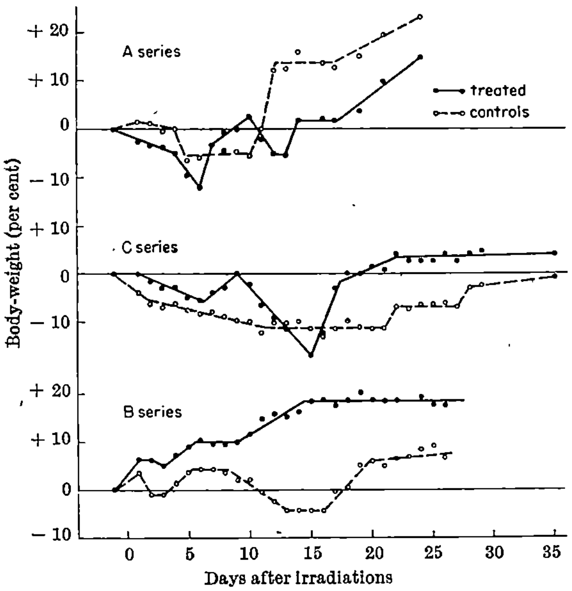

Fig. 2. Change in average body-weight relative to average body-weight on the day before irradiation for series *A*, *C* and *B*

died in either of the series *A* or *C*, although during the same period the highest toll was taken from the control groups. The lower curve in Fig. 1 shows the difference in the mortality-rate of treated and controls. This curve runs definitely anti-parallel to the relative leucocyte count (upper curves).

The body-weight of the animals was measured daily. Fig. 2 shows the change in the average body-weight for treated and controls in series *A*, *C* and *B*. The greater increase in weight after recovery in series *A* and *B* is due to the circumstance that in these series very young animals which were not fully developed were used. All three series show different behaviour of treated and controls. In both high-lethal series *A* and *C*, the weight curve of the treated shows a maximum on the 9th post-irradiation day, which coincides with the maximum in the relative leucocyte count in Fig. 1 and with the low-mortality period of the treated groups in series *A* and *C*. The weight-curves of the controls do not show such a maximum.

The weight-curve of the treated group in the low-lethal series *B*, although indicating a small minimum on the third day, increases thereafter continuously. This pattern of the weight-curves indicates that radiation injury was practically fully compensated in this low-lethal series through previous magnetic treatment. None of the treated mice died in this series.

A further effect of the magnetic treatment is indicated in the relative weight of spleens. (Spleens were removed and weighed within 2 hr. after death had occurred.) In series *A* the average spleen weight of treated and controls was the same. In series *C*, where the animals underwent a previous irradiation 44 days earlier, the spleen weight of the treated was only 57 per cent of that of the controls. The difference is significant on a probability-level less than $1/10^8$; and indicates that the treated animals were not affected by their first, low-lethal irradiation 44 days earlier and, therefore, their spleens did not pass through a transitory hyperplasia[5] as a consequence of the recovery process from leucopænia.

The hæmatological counts were made by Miss M. Walker at St. Francis Hospital, Evanston, Illinois. Acknowledgment is due to the staff of the Cook County Hospital, to Dr. I. F. Hummon, Dr. M. F. Magalotti and Miss D. Scully for their kind co-operation in the irradiation of the animals. The experiments were performed in our laboratory in Evanston, Illinois, and assisted by the Dorothy Shattuck-Stensland Foundation.

ELECTROPHORETIC SEPARATION AND CLASSIFICATION OF BLOOD PLASMA ESTERASES

By Dr. KLAS-BERTIL AUGUSTINSSON

Institute of Organic Chemistry and Biochemistry, University of Stockholm

THE specificity of cholinesterases present in the plasmata of various mammalian species is fairly well known and aliphatic esterases and lipases have also been studied, though in less detail, using simple esters and triglycerides as substrates[1–3]. For most animal species, it is still unknown whether the plasma contains, in addition to a cholinesterase, aliphatic esterases or/and lipases. The presence of an aromatic esterase in human plasma has been proposed[4] and Aldridge[5] introduced a nomenclature, a most satisfactory one as will be demonstrated below, for esterases hydrolysing *p*-nitrophenyl acetate, propionate and butyrate. The A-esterase is the enzyme which splits acetate at a higher rate than butyrate and is resistant to organophosphorus compounds; the B-esterase is inhibited by such compounds. It is not known, however, whether A- or/and B-esterases have the ability to hydrolyse aliphatic substrates or whether it is justifiable to call either A-esterase or both A- and B-esterases 'aromatic esterases'. Like the aliphatic esterases, they differ from the cholinesterases in being resistant to physostigmine.

Except for a study of the A- and B-esterases of rabbit and guinea pig plasmata[6], no attempt has been made so far to separate the various esterases electrophoretically. The object of the present investigation was to explore the usefulness of electrophoresis for such separations, to compare the esterase patterns of various vertebrate plasmata, and to propose a classification based on such patterns. The results showed that vertebrate plasmata contain three types of esterases; some plasmata contain all three types, others two and still others only one. When designating these enzymes, the nomenclature generally accepted by most authors in this field was followed so far as possible. The characteristic features of these esterases as revealed by the present study are summarized below; it will be understood that within each group there are species variations in the properties of the individual enzymes within the group.

A-esterases (arylesterases): typical aromatic esterases which hydrolyse phenyl acetate at a higher rate than phenyl butyrate: aliphatic esters are normally not attacked. They are resistant to both organophosphorus compounds and physostigmine, and have, in most cases, the greatest electrophoretic mobility of the three esterase groups, moving together with or close to the albumin components.

B-esterases (aliphatic esterases, lipases): both aliphatic and aromatic esters are hydrolysed; there exist acetyl-, propionyl- and butyryl-B-esterases, and choline esters are not hydrolysed. They are sensitive to organophosphorus compounds, but resistant to 10^{-5} *M* physostigmine; some B-esterases are sensitive to higher concentrations of the latter compound. The B-esterases move electrophoretically more slowly than the A-esterases (eel plasma is an exception), but more rapidly than the C-esterases; they are always found in the α_1-globulin fraction or a fraction close to that component.

C-esterases (cholinesterases): choline esters are split at a higher rate than both aliphatic and aromatic esters, the latter usually being hydrolysed at a lower rate than aliphatic esters or not at all; the specificity regarding the acyl group varies greatly. These esterases are sensitive to both organophosphorus compounds and physostigmine, the latter giving 100 per cent inhibition in 10^{-5} *M* or lower concentration. They have the slowest electrophoretic mobility of all plasma esterases (frog plasma is an exception), normally migrating between the α_2- and β-globulins. (It is not my intention to add a new term to all those already existing for these enzymes; 'C-esterase' is used here only for practical reasons when these esterases are discussed in relation to the A- and B-esterases, and because it is the third esterase coming out in electrophoresis.)

Plasma was prepared from heparinized blood, and was free from all cells, including thrombocytes. Aliphatic, aromatic and choline esters were tested as substrates. The substrates used were the acetyl (Ac), propionyl (Pr), butyryl (Bu) esters of the following radicals, *iso*-amyl, glycerol (for example, tributyrin), phenyl and choline; also, acetyl-β-methylcholine, benzoylcholine, succinylcholine, the carbon analogue of acetylcholine (3,3-dimethylbutylacetate), 'Tween 20' (polyoxyethylene sorbitan monolaurate), procaine hydrochloride, atropine sulphate, cocaine hydrochloride, and heroin. Choline esters were all as iodides. Eight compounds were selected as inhibitors from those frequently studied as selective enzyme inhibitors[7] in recent esterase studies: physostigmine salicylate, tetra-*iso*propylpyrophosphoramide, mipafox (*bis*-mono*iso*propylamino fluorphosphine oxide), 'Astra 1397' (10-(1-diethylaminopropionyl) phenothiazine hydrochloride), 3318*CT* (*bis*-(piperidinomethyl coumaranyl-5)ketone), 62*C*47 (1,5-*bis*(4-trimethylammoniumphenyl)pentane - 3 - one diiodide), atoxyl, and quinine sulphate. The active fractions obtained in electrophoresis were dialysed against a bicarbonate buffer prior to testing against the inhibitors.

Electrophoresis was carried out on cellulose columns[8] (3 cm. × 40 cm.) in veronal buffer (pH 8·4, $\mu = 0{\cdot}1$) at 5–11° C., using 5 ml. buffered plasma for each experiment and a current of 60 m.amp.; the duration of runs was 30 hr. The protein concentration of successive 2·8 ml. fractions of the eluate was estimated by a modified Folin method[9], and the esterase activities of the fractions estimated manometrically by the Warburg technique[7].

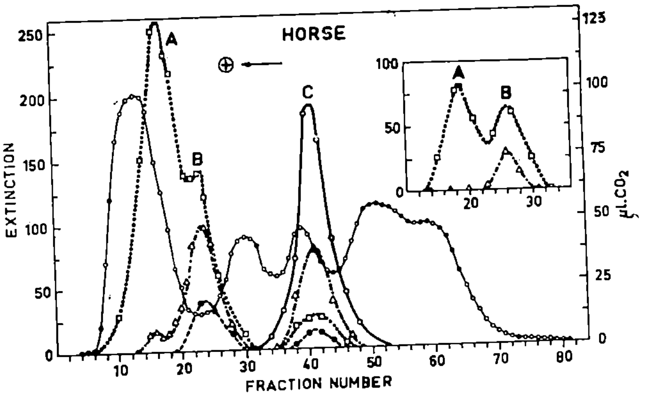

Fig. 1. Distribution of protein and esterase activity after column electrophoresis of horse plasma. The protein content (measured by the extinction at 700 mμ) and esterase activity (expressed at μl. carbon dioxide/30 min./ml. fraction) are plotted as ordinates against the fraction numbers as abscissæ. For convenience in presentation, the esterase activities have been multiplied by the factors, shown below in brackets, before plotting. ○—○, protein concentration; □ . . . □, phenyl acetate (0·05); △–.–△, phenyl butyrate (0·1), tripropionin (0·15, peak *B*; 0·3, peak *C*); ● - - - ●, tributyrin (0·1), *iso*-amyl butyrate (0·1, peak *B* only); ○–○, butyrylcholine (0·1), propionylcholine (0·16), benzoylcholine (0·8).

The insert is the electropherogram of a mixture of 3·8 ml. purified A-esterase and 8·0 ml. purified B-esterase from the peak fractions of *A* and *B*, main diagram, showing clearer resolution of A- and B-esterases. □ . . . □, phenyl acetate (0·4); △–·–△, phenyl butyrate (0·4)

Fig. 1 shows in detail the results of a single separation using horse plasma. It will be seen that, depending on the substrate, esterase activity was maximal in one or more of three clearly separated fractions. The three peaks of activity are designated *A*, *B* and *C*. It is a reasonable inference that these three peaks are due to the presence of three distinct enzymes, each with a different, and characteristic, electrophoretic mobility. The family of curves in each peak gives the substrate specificity of the enzymes responsible for it; a comparison of the esterase peaks with those of protein concentration indicates the relation of the enzyme proteins to the main protein components of the plasma and enables the specific activity of the various fractions to be estimated.

Esterases separated in this way were studied further by means of selective inhibitors and by submitting them to a second electrophoretic separation. The insert diagram in Fig. 1 shows that a mixture of A- and B-esterases can be more completely resolved by further electrophoresis and that each enzyme again travels as a single component.

Fig. 2 shows in simplified diagrams the results with nine further plasmata and Fig. 3 summarizes the plasma esterase pattern of all the species studied as revealed by combined studies of electrophoretic mobility, substrate specificity and sensitivity to inhibitors. The characteristics of the various plasmata studied will now be briefly summarized.

Horse (Fig. 1). This plasma contains all three types of esterases. The A-esterase is a typical acetylarylesterase, being resistant to all inhibitors studied. The B-esterase has a low specificity, and is a typical propionylesterase, the propionates in both the aromatic and aliphatic series of substrates being hydrolysed at a higher rate than the corresponding acetates and butyrates. It differs from most B-ester-

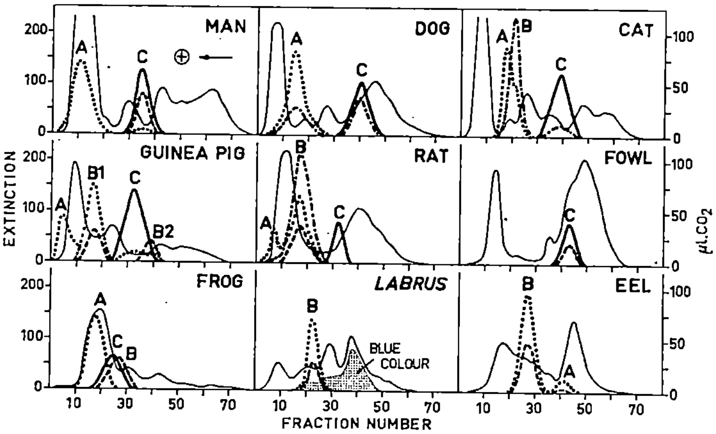

Fig. 2. Distribution of protein and esterase activity after electrophoretic separation of vertebrate plasmata. Conditions as for Fig. 1

Man: *A*, ..., phenyl acetate (0·01), phenyl butyrate (1·0). *C*, ——, butyrylcholine (0·1); – – –, tributyrin (0·4), [phenyl butyrate (0·1), benzoylcholine (0·8); ...., phenyl acetate (0·01).

Rat: *A*, ..., phenyl acetate (0·05). *B*, –.–., phenyl butyrate (0·05); ...., phenyl acetate (0·05); – – –, tripropionin (0·1), *iso*-amyl acetate (0·32), 'Tween' (0·2). *C*, ——, propionylcholine (0·8), butyrylcholine (1·0), phenyl acetate (1·0), phenyl butyrate (4·5).

Fowl: *C*, ——, propionylcholine (0·4); – – –, tripropionin (0·4), phenyl acetate (0·4), phenyl butyrate (0·4).

Frog: *A*, ..., phenyl acetate (0·02), phenyl butyrate. *B*, – – –, tripropionin (0·2), phenyl butyrate. *C*, ——, butyrylcholine (0·2).

Labrus: *B*, ..., phenyl butyrate (0·05), 'Tween' (0·2); – – –, tripropionin (0·1); shaded area refers to the blue-coloured fractions measured spectrophotometrically at 645 mμ.

Eel: *B* and *A*, ..., phenyl acetate (0·005), *iso*-amyl butyrate (0·15), triacetin (0·05); – – –, heroin (0·1).

ases in being resistant to tetra-*iso*propylpyrophosphoramide (but not to mipafox); this is characteristic also of the B-type esterases present in fish plasmata. The C-esterase is a typical butyrylcholinesterase with the same low specificity and similar inhibition pattern as that of human plasma. Phenyl acetate and phenyl butyrate are both split by all three esterases, the relative rates of hydrolysis by the A-, B- and C-esterases being 1·8 : 1 : 0·2 for the acetate and 1 : 5 : 4 for the butyrate. It will be seen that the A- and B-esterases migrate between the albumin and α_1-globulin components and the C-esterase between the α_2- and β-globulins.

Man (Fig. 2). Only A-esterase and C-esterase are present. The former hydrolyses phenyl acetate at a rate which is approximately 100 times greater than the hydrolysis-rate of phenyl butyrate; the enzyme is resistant to all inhibitors studied in this series and does not hydrolyse aliphatic esters. The C-esterase is a typical butyrylcholinesterase with low specificity, that is to say, the butyrates of both phenol and aliphatic alcohols (including glycerol) are split at relatively high rates. This enzyme is also capable of hydrolysing benzoylcholine and succinylcholine, as well as the carbon analogue of acetylcholine, procaine, atropine, and 'Tween 20'. It is sensitive to all inhibitors, physostigmine being the most potent compound (pI_{50} 7·7), and 62*C*47 and quinine the less potent ones (pI_{50} 5·0).

Dog (Fig. 2). The esterase pattern of this plasma closely resembles that of human plasma, in the first place by being devoid of B-esterase. The A-esterase is a typical acetyl-arylesterase, and the C-esterase is a butyrylcholinesterase of low specificity; the triglycerides are split at comparatively low rates. The C-esterase is otherwise similar to other butyrylcholinesterases present in the plasmata of various animal species.

Cow. An acetyl-A-esterase is the only esterase present in significant amounts. The plasma does not contain any B-type esterase, and the C-esterase, present in low concentration, is a propionylcholinesterase which is inhibited by excess substrate concentration. This enzyme is sensitive to those compounds (62*C*47 and 3318*CT*) which are regarded as being selective inhibitors of acetylcholinesterase (of erythrocytes and nerve tissue), and resistant to 'Astra 1397'.

Pig. The plasma has low, medium or high esterase activity, due mainly to the great individual variation in acetyl-arylesterase concentration. A B-esterase is probably not present. The properties of the C-esterase, also present in low concentration, differ from all other cholinesterases studied in this series regarding specificity, confirming previous results[3,10]; it does hydrolyse benzoylcholine, which has been a subject of discussion, and its sensitivity to inhibitors is otherwise similar to that of butyrylcholinesterases.

Cat (Fig. 2). Three esterases are present, of which the A-esterase is a propionyl-arylesterase. The B-esterase splits a variety of esters, the hydrolysis-rates being greatly dependent on the configuration of the alcoholic group; tripropionin is split at a higher rate than tributyrin, the reverse being true for the *iso*-amyl derivatives. The C-esterase is a butyrylcholinesterase similar to the human and horse C-esterases, except for being less sensitive to atoxyl and quinine.

Guinea pig (Fig. 2). Both A- and B-esterases are present in high concentration. The propionates and butyrates are split by the B-esterase at about the same rate, and more rapidly than the acetates. The

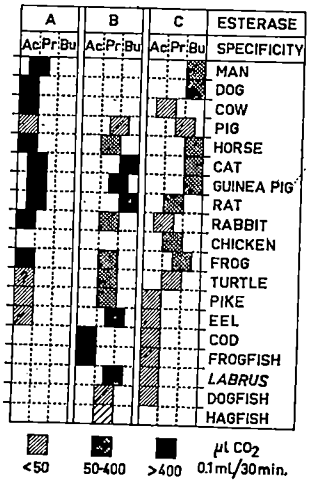

Fig. 3. Plasma esterase patterns of vertebrates

hydrolysis of 'Tween 20', the rate of which is comparatively high with this plasma, is catalysed by this enzyme. Guinea pig plasma also contains a second B-esterase (B 2), moving at a higher rate in electrophoresis than the C-esterase, and being sensitive to tetra-*iso*propylpyrophosphoramide but not to physostigmine. Both B-esterases are capable of hydrolysing *iso*-amyl butyrate. This ester is not split by the C-type esterase, which is a butyrylcholinesterase. It will be noted that all four esterases traced on the electropherogram are able to hydrolyse phenylacetate.

Rabbit. This plasma contains at least three esterases. Phenyl acetate and phenyl butyrate are hydrolysed by both an A-esterase (or probably two A-type esterases, running close together in electrophoresis) and a B-esterase; the latter enzyme has the properties of a propionylesterase and its concentration varies considerably from animal to animal. The C-esterase is an acetylcholinesterase (of a type found in the erythrocytes and nervous tissue). The properties are similar to those of such an enzyme in the following ways: splitting acetylcholine and propionylcholine at a higher rate than butyrylcholine; in being resistant to 'Astra 1397', atoxyl and quinine; in being less sensitive to tetra-*iso*propylpyrophosphoramide and mipafox than most other plasma cholinesterases, and very sensitive to 62*C*47; in that the activity is inhibited by high concentrations of acetylcholine.

Rat (Fig. 2). The esterase properties are very much like those of guinea pig plasma; the second B-esterase present in the latter plasma is, however, missing in rat plasma. The rat is the only mammalian species studied in this series which has a typical propionylcholinesterase in its plasma, confirming a previous observation[3]. In some respects, concerning inhibitory effects of various compounds, this enzyme differs from the butyrylcholinesterases.

Fowl (chicken; Fig. 2). This plasma is unique among those examined in being devoid of both A- and B-esterases. The B-type esterase described by Aldridge[5] is actually identical with the propionylcholinesterase present which splits acetyl-β-methylcholine at a comparatively high rate. The hydrolysis-rates of four different substrates, propionylcholine, tripropionin, phenyl acetate and phenyl butyrate, were all found to be influenced to the same degree by the eight inhibitors tested. The enzyme is extremely sensitive to mipafox pI_{50} 9·0) and is more or less resistant to 62*C*47, 3318*CT*[11], atoxyl and quinine.

Frog (*Rana temporaria*; Fig. 2). A-, B- and C-esterases are present, the A-esterase having similar properties to other plasma A-type esterases studied. The B-esterase differs from other B-type esterases in being somewhat sensitive to physostigmine (pI_{50} 4·5). Choline esters, however, are not hydrolysed by this enzyme, the C-esterase present being responsible for this reaction. The C-esterase is a propionylcholinesterase which splits butyryl choline at a relatively high rate, but differs otherwise from the C-esterase of chicken plasma. The most significant property of frog C-esterase is its relatively high electrophoretic mobility, higher than that of the B-esterase. The plasma of the toad, *Xenopus laevis*, contains an A-esterase, a propionyl- or/and butyryl-B-esterase, and a butyrylcholinesterase (in low concentration).

Eel (*Anguilla anguilla*; Fig. 2). This plasma is characterized by its ability to split aromatic esters and triglycerides (especially those of butyric acid) at a very high rate. The material seems to be the richest animal source of 'lipase' activity ever described; in this respect it is 100 times more active than human plasma, and has the same high esterase activity for phenyl butyrate as certain electric organs for acetylcholine. The enzyme is of the B-type and splits heroin at a comparatively high rate. In addition, an A-esterase in low concentration is present. It has the properties of an acetylesterase, and has a higher electrophoretic mobility than the B-esterase. Eel plasma also contains, as most fish plasmata, a C-esterase, the properties and sensitivity to inhibitors of which are those of an acetylcholinesterase.

Pike. The esterase pattern is similar to that of the eel plasma, except for lower enzyme activity and specificity more pronounced for propionates; heroin is hydrolysed at a low rate. Most of the esterase activity is due to a B-esterase, which is very sensitive to mipafox (pI_{50} 9·1) and less so to physostigmine (pI_{50} 4·8). The C-esterase, present in low concentration, is an acetylcholinesterase.

Cod. A B-esterase of the acetyl type is characteristic of this plasma. It splits heroin at a comparatively high rate and is sensitive to mipafox but not to tetra-*iso*propylpyrophosphoramide. An acetylcholinesterase is also present in low concentration.

Frogfish (*Lophius piscatorius*). The B-esterase, present in high concentration, is a typical acetylesterase which splits heroin at a high rate. It is sensitive to mipafox but not to tetra-*iso*propylpyrophosphoramide, and is also inhibited by physostigmine (pI_{50} 4·0). An acetylcholinesterase is present in low concentration.

Wrass (*Labrus berggylta*; Fig. 2). The B-esterase present splits butyrates and propionates at a higher rate than acetates, and is sensitive to mipafox but not to tetra-*iso*propylpyrophosphoramide. 'Tween' is split at a relatively high rate by this enzyme. The C-esterase, of low concentration, is an acetylcholinesterase. The blue colour characteristic of the labride plasmata is due to the presence of a chromoprotein (absorption maxima at 390, 600 and 645 mμ) which moves electrophoretically at a higher rate than other proteins present.

Dogfish (*Squalus acanthias*). The plasma has a very low esterase activity, being due to a propionyl-B-esterase and an acetylcholinesterase.

Hagfish (*Myxine glutinosa*). This plasma contains an esterase (probably an acetyl- or propionyl-B-esterase) in trace amounts. No other esterases have been detected.

A full account of this work will be published elsewhere. It was supported by a grant from the Swedish Natural Science Research Council. Grateful acknowledgments are due to Dr. V. P. Whittaker, of the Agricultural Research Council Institute of Animal Physiology, Cambridge, for valuable comments on the presentation of this work, and to Miss Toril Isachsen and Mrs. Gunnel Jonsson for skilled technical assistance.

Formaldehyde as an Acceptor Aldehyde for Transketolase, and the Biosynthesis of Triose

THE enzyme transketolase is biologically widely distributed, and, in presence of thiamine pyrophosphate and magnesium ions, transfers the ketol group or 'active glycolaldehyde' (CH$_2$OH.CO . . .H) from a variety of ketose phosphates (sedoheptulose 7-phosphate, D-fructose 6-phosphate, D-xylulose 5-phosphate), from certain free ketoses (L-erythrulose, D-xylulose) and from hydroxypyruvic acid to certain 'acceptor aldehydes', thus synthesizing new ketoses. The 'acceptor aldehydes' hitherto recognized are D-glyceraldehyde 3-phosphate, D-ribose 5-phosphate, D-erythrose 4-phosphate and 2-deoxyribose 5-phosphate; also free glyceraldehyde and glycolaldehyde (for reviews see refs. 1–3). Acetaldehyde and formaldehyde are stated not to be acceptors[4], but the former appears in our preliminary tests to be weakly active.

Formaldehyde, on the other hand, we find reacts quite effectively as an acceptor when pure lithium hydroxypyruvate[5] is the donor. The product formed corresponds chromatographically, chemically and enzymically with dihydroxyacetone:

$$\mathrm{CH_2OH.CO.COOH + H.CHO \rightarrow CH_2OH.CO.CH_2OH + CO_2}$$

Table 1 shows the manometric and other results. Table 2 shows the chromatographic identification.

Table 1. FORMALDEHYDE AS 'ACCEPTOR' FOR TRANSKETOLASE ACTION

Transketolase was prepared by the method of de la Haba, Leder and Racker (ref. 4); a sample purified by column adsorption kindly supplied by Dr. E. Racker behaved similarly. Contents of vessels: transketolase (500 μgm.), thiamine pyrophosphate (0·2 μmole), magnesium chloride (5 μmoles), pH 6·6 buffer to total volume of 2·5 ml. Substrates as below (formaldehyde or hydroxypyruvate, 20 μmoles of each). The values given are in μmoles after 2 hr. incubation at 37° C.

Substrate	Hydroxy-pyruvate	Hydroxy-pyruvate + formaldehyde	Hydroxy-pyruvate + formaldehyde (no enzyme)
Carbon dioxide produced	1·2	15·2	0
Formaldehyde utilized	0	15·7	0·8
Hydroxypyruvate utilized*	2·6	18·0	2·8
Triose formed†	none	+++	none

* Spectrophotometrically by specific dehydrogenase (cf. ref. 11).

† By glycerokinase and adenosine triphosphate (manometrically and also by formation of alkali-labile phosphate); by formation of methyl glyoxal on distillation with acid; and by chromatography (Table 2).

Table 2. CHROMATOGRAPHIC IDENTIFICATION OF DIHYDROXYACETONE FORMED

Deionized vessel-contents (Table 1) were concentrated *in vacuo* and analysed by descending chromatography on Whatman No. 1 paper; detection by aniline phosphate spray

Solvent (parts by vol.)	R_F values Unknown	Dihydroxyacetone	Glyceraldehyde	Erythrulose	Threose
Phenol/water (4 : 1)	0·81	0·81	0·44	0·72	0·65
Butanol/acetic acid/water (4 : 1 : 5)	0·45	0·45	0·49	0·36	0·43
Ethylmethyl ketone/acetic acid/4 per cent boric acid (9 : 1 : 1)	0·48	0·49	0·14	0·38	0·36

The interaction of transketolase with the numerous biological sources of formaldehyde opens the possibility of various new metabolic routes. The dihydroxyacetone formed in the above reaction is readily phosphorylated by 'glycerokinase' prepared from rat liver by the method of Bublitz and Kennedy[6]: the resulting phosphate could therefore enter the triose phosphate and hexose phosphate pools. Another route from L-serine to hexose, alternative to that proposed for phosphoserine by Ichihara and Greenberg[7], might proceed via serine aldolase (giving formaldehyde and glycine) in conjunction with the formation of hydroxypyruvate from L-serine by the specific transaminase of Sallach[8]. Transketolation of the hydroxypyruvate to formaldehyde could thus provide dihydroxyacetone. Whether the observed transformation in the rat of [3-^{14}C]serine[9] and of [2-^{14}C and 3-^{14}C] hydroxypyruvate[10] to liver glycogen actually follows this pathway is being investigated. The extent of formation of dihydroxyacetone from donors other than hydroxypyruvate and the question of reversibility of these reactions are also being studied by us.

Thanks are due to Mr. R. Carrick James for technical assistance.

A Procedure for the Purification of Sirenin

SIRENIN (I am indebted to Dr. A. Vegis for suggesting, what seems to me, this aptly descriptive name) is the name, used here for the first time, for the chemotactic sexual hormone from the water-mould *Allomyces* which attracts the male gametes and is produced by the female gametes[1]. This hormone has now been produced and purified.

Fernbach flasks (1,800 ml.) containing 500 ml. of yeast extract–starch medium[2] were inoculated with mycelial fragments of the female strain *F*-2[1] and incubated for two days on shakers at 30° C. The plants obtained were washed with copious amounts of tap water and then placed in thin layers in dishes where they were just covered with double-distilled water. This water was replaced after 3, 8 and 24 hr., thereby inducing gamete formation and release for a total of 48 hr. The aqueous solutions, containing approximately 25–100 µgm. sirenin per litre, were freed of gametes by passage through Seitz filters and the solutes adsorbed on 'Norit *FNX* Special' charcoal used at the rate of 5 gm. per 500 ml. of solution.

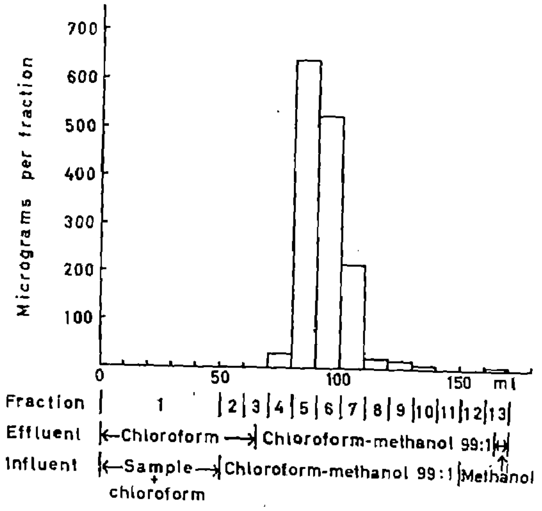

Fig. 1. The fractionation of sirenin on a silicic acid column

The solutes were eluted from the charcoal with chloroform, evaporated to dryness at room temperature, and the residue then extracted with water. Upon removing the water at 30° C., the residue was taken up in 3–10 ml. of redistilled chloroform, thereby providing the sample for fractionation on a silicic acid column[3]. The programme followed and the fractionation obtained are shown in Fig. 1. The last addition was followed by 50 ml. of chloroform to prepare the column for the next run.

The details of this procedure for purifying sirenin were clarified shortly before this investigation had to be terminated. Consequently, the various small samples in the laboratory were each passed through the column; fractions 1, 12, and 13 were discarded and the remaining fractions from all runs mixed and re-run. Fractions 5 and 6 of this final run (Fig. 1) were mixed, the solvent evaporated, and the residue analysed. A clearly detectable response in the bioassay[1] was observed with a concentration of 10 μgm. per litre. The fact that sirenin was not retained on 'Dowex' 2 and 50 ion exchange columns indicated that the molecule is neutral. Characteristic absorption peaks were absent from the ultra-violet spectrum.

The 6μ region of the infra-red absorption spectrum displayed a not very well resolved band consisting of several overlapping absorption bands. Of these bands, one at 5·63μ indicated the presence of a lactone ring, another at 6·85 indicated the presence of keto and/or aldehyde functions, and perturbances in the 5·95 to 6·03μ region suggested double-bond carbon and/or carbon–nitrogen functions. There was no evidence of aromatic rings and no positive indications of hydroxy and carboxyl functions.

The mass spectrum showed no very distinctive characteristics. However, peaks corresponding to *m/e* 31, 44, and 58, which often reflect ionized fragments representing methoxy, aldehyde and unsubstituted ketone (— CH_2COCH_2 —), respectively, were stronger than to be expected unless such groups were actually present in the molecule. There was in this spectrum, too, no indication of aromatic rings. The maximum molecular weight indicated by the mass spectrum was 386.

The ultra-micro[4] elementary analysis was consistent with the preceding inferences. There was found: C, 61·6 (± 1·5) per cent; H, 8·8 (± 0·3) per cent; N, 3·4 (± 0·3) per cent; and O (by difference), 26·2 per cent. On the basis of the formula $C_{21}H_{36}O_7N$ the minimum molecular weight is 414. This weight is of the same order of magnitude as that indicated by the mass spectrum. These tentative analyses are presented here since they may be useful to others in the determination of the structure of sirenin.

This work was performed in the Institute of Physiological Botany, University of Upsala, where I was on sabbatical leave, with the assistance of a fellowship from the John Simon Guggenheim Memorial Foundation, and was supported, in part, by a research grant (*G*1291) from the National Science Foundation.

I wish to acknowledge the assistance of the following: Prof. Nils Fries, whose guest I was at the Institute; Dr. A. Rosenberg for making and interpreting the infra-red spectra; Prof. P. E. Lindahl and his assistant for the ultra-violet spectra; Prof. E. Stenhagen and Dr. R. Ryhage for making and interpreting the mass spectra; and Mr. W. Kirsten for the ultra-micro elementary analysis. A more detailed report of this work is being published in *Physiologia Plantarum*.

Formation of Lactate from Acetoacetate in the Perfused Heart

Seaman[1] and Davies[2] have recently described enzyme systems in protozoa and pig heart which catalyse the oxidative condensation of two molecules of acetyl coenzyme *A* to produce succinate.

$$2CH_3.\mathit{CoSCoA} + \mathit{DPN}^+ \rightarrow HOOC.CH_2.CH_2COOH + 2\mathit{CoA} + \mathit{DPNH} + H^+ \quad (1)$$

The existence of the enzyme in rat tissues is at present debatable[1]. The reaction is reversible, and, in fact, the equilibrium is very much in favour of cleavage of the succinate, but it may be driven in the direction of synthesis by the addition of suitable systems capable of oxidizing reduced diphosphopyridine nucleotide[2]. Since succinate may be transformed into pyruvate either through decarboxylation of oxaloacetate or oxidative decarboxylation of malate, reaction 1 is the key to a synthesis of carbohydrate from fat with net gain of carbon.

Recent experiments with isolated rat diaphragm in which the muscle was incubated with glucose and acetate or acetoacetate[3] have shown that significantly more lactate is produced, when acetoacetate is present, than can be accounted for by disappearance of glucose and glycogen. With acetate as substrate, lactate appearing exactly balanced the loss of carbohydrate. Since acetoacetate can be cleaved in muscle to acetyl coenzyme *A*, it was tentatively concluded that the pathway outlined above, followed by reduction of pyruvate to lactate, was operating in this tissue. The reason why net lactate synthesis took place from acetoacetate and not from acetate was thought to be the very high rate of uptake of the former compound.

Table 1. HEARTS FROM FASTED MALE ALBINO RATS PERFUSED WITH KREBS–RINGER BICARBONATE

Three periods, volume in each period 20 ml. (first period, 1·5 mgm./ml. glucose; second period, no glucose; third period, no glucose ± acetoacetate, 0·01*M*; concentration of sodium chloride in Ringer solution being reduced by 0·01 *M* when acetoacetate was present). 0·5-ml. samples removed from system at 10 min. intervals for estimation of lactate (ref. 5) and acetoacetate (ref. 6). The tabulated figures represent rates of lactate production ± standard deviation during each period; negative values indicate disappearance of lactate. A correction has been made for carry-over of lactate from one period to the next

Solution \ Time	50–60 min.	60–70 min.	70–80 min.	Final glycogen (μmole/gm.)
	Lactate produced (μmole/gm./hr.)			
Control (10)	6·9* ± 4·9	−1·8 ± 3·9	−0·8 ± 3·2	2·7 ± 1·3
Acetoacetate (10)	18·1* ± 14·4	3·0 ± 12·7	−7·6 ± 11·1	2·8 ± 0·7
	Acetoacetate utilized (μmole/gm./hr.)			
Control	—	—	—	*$t = 3{\cdot}18$
Acetoacetate	32·1 ± 15·5	26·7 ± 21·8	21·4 ± 16·9	$P < 0{\cdot}01$

The results were not, however, beyond doubt, in that proof of the formation of 'excess' lactate depends on the determination of the uptake of glucose, initial glycogen-content, final glycogen-content and lactic acid production, all of which values are subject to error. It was decided to repeat the experiments with a system which could be stripped of carbohydrate before adding the lactate precursor. The isolated perfused rat heart was found very suitable.

Hearts from fasted rats weighing 150–180 gm. were perfused, essentially according to the method of Bleehen and Fisher[4], in an apparatus which permitted the replacement of all the circulating perfusate when desired. Glucose was added to the perfusion fluid while the heart was being established; the fluid was then changed to one without glucose. After perfusion for 30 min. with this solution, the heart glycogen, which was initially 20·6 ± 4·2 μmoles/gm., had fallen to 3·7 ± 1·6 μmoles/gm. (mean values), and lactate had ceased to enter the perfusion fluid. There was indeed evidence of a slow disappearance of lactate, presumably by oxidation, towards the end of the period (Fig. 1). A second group of hearts was perfused for three periods: for 20 min. with Ringer + glucose; for 30 min. with Ringer − glucose; and for 30 min. with Ringer − glucose ± acetoacetate (0·01 *M*). The results are shown in Table 1.

Six of the ten hearts perfused with acetoacetate produced significantly more lactate during the first 10 min. of period 3; the average production for the whole group was 11·2 μmole/gm./hr. more than ten controls. Production fell off during the next 20 min. and a slow disappearance of lactate began (Fig. 1).

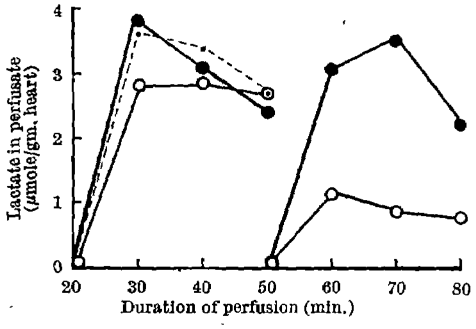

Fig. 1. Production of lactate by perfused hearts: perfusate changed at 20 and 30 min. ○—○, Control; ●—●, acetoacetate in period 3; ● - - - ●, hearts stopped at 50 min.

Simultaneously, the rate of uptake of acetoacetate fell off. There was always significantly more lactate in the perfused fluid when acetoacetate was present. The only carbohydrate sources for this lactic acid were from glycogen, which fell from 3·7 μmoles/gm. at 50 min. to 2·7 (2·8) μmoles/gm. at 80 min., accounting for 2·0 μmoles/gm. lactate, and intracellular lactate. By experiment, the intracellular lactate contents of hearts at the end of period 2 was found to be 4·8 ± 1·9 μmoles/gm. This, together with glycolysis, could just account for the lactate produced by the control hearts, but it is concluded that the extra lactate in the acetoacetate – perfused hearts can only have come from this substrate.

The significance of lactate may be that pyruvate reduction is coupled with succinate synthesis by means of reduced diphosphopyridine nucleotide, and so drives reaction (1) from left to right. Capraro and Milla[7] found that the injection of acetoacetate or β-hydroxybutyrate into dogs was followed by an almost immediate rise in blood lactate; Nath and Chakrabarti[8] reported that daily injection of acetoacetate over a period of time caused a gradual rise in the blood lactate-level in rabbits. In the present experiments, perfusion with acetoacetate did not alter the glycogen content of the hearts, so that there was no direct synthesis of glucose from acetoacetate in the muscle itself; it appears to be generally agreed that the heart cannot synthesize glycogen from exogenous lactate[9] at least. However, in the intact animal, glycogen can be synthesized from lactate in the liver, so that a synthesis of glucose from fat would be possible by means of a cycle running from liver to muscle to liver, in ketotic organisms. Recent experiments[10] on feeding high-fat diets to obese human subjects can be explained in these terms. Gluconeogenesis by such a mechanism can only be important, of course, in extreme conditions of starvation or diabetes when the level of ketone bodies in the blood is much above normal.

Removal of Internally Deposited Plutonium

ATTEMPTS to remove plutonium from the mammalian system may be placed in two categories: (1) prevention of deposition by treatment within eight hours after exposure to plutonium and (2) removal of plutonium after it has become 'fixed' in the tissues. Zirconium citrate and ethylenediamine tetraacetic acid have been used with some success in the first category but with only limited success in removing firmly bound plutonium[1]. Among compounds tested in this laboratory, diethylenetriamine

Table 1. EFFECT OF CHELATING AGENTS ON PLUTONIUM DEPOSITION AND REMOVAL AS PERCENTAGE OF DOSE ADMINISTERED PER GRAM OF DRY TISSUE

The dosage was 0·3 m.mole per rat of each material with 0·2 m.mole calcium gluconate being administered with the chelating agent. There were 6–10 rats in each group. Results include the 95 per cent confidence interval around the mean

Treatment	Concentration in the tissue			
	Bone	Liver	Spleen	Kidney
Category 1 (Prevention of deposition)				
Saline controls	6·6 ±0·5	9·1 ±1·4	18·0 ±2·0	2·4 ±0·1
Ethylenediamine tetraacetic acid	4·6 ±0·3	4·9 ±0·7	10·7 ±2·2	1·4 ±0·1
Diethylenetriamine pentaacetic acid	0·87±0·06	2·7± 0·3	2·4 ±0·3	1·6 ±0·2
Category 2 (Removal)				
Saline controls	7·8 ±0·9	1·8 ±0·4	2·9 ±0·6	0·60±0·13
Ethylenediamine tetraacetic acid	6·3 ±0·6	1·2 ±0·2	1·2 ±0·2	0·45±0·10
Diethylenetriamine pentaacetic acid	4·0 ±0·2	0·23±0·04	0·93±0·26	0·30±0·10

pentaacetic acid has proved to be superior in both categories.

Adult Sprague–Dawley rats were injected intravenously with about 1 μc. of plutonium as the citrate. A single, intraperitoneal treatment was administered 1 hr. after the plutonium in the category 1 experiment, whereas several treatments a week, beginning 38 days after the plutonium injection and running for four weeks, were given in the removal experiment. Rats in the category 1 experiments were killed two days after the plutonium injection, and in the long-term experiment on the sixty-fourth day.

As shown in Table 1, diethylenetriamine pentaacetic acid is consistently more efficient than ethylenediamine tetraacetic acid in eliminating plutonium. The prompt administration of the former reduced the skeletal plutonium content from 61 per cent of the administered dose in the controls to about 9 per cent, whereas animals treated with the latter retained 44 per cent of the administered dose. The relatively poor results obtaining by administering diethylenetriamine pentaacetic acid promptly in preventing deposition in the kidney may be due to the short duration of the experiment (two days), since in longer experiments it was more effective than ethylenediamine tetraacetic acid in removing plutonium from the kidney. Its effectiveness as a therapeutic agent is also indicated in the removal of firmly bound plutonium. The four-weeks treatment reduced the plutonium content of bone by about one-half, and also markedly reduced the plutonium content of soft tissues. It should be noted that these experiments are of a comparative nature and do not represent treatment at the maximum tolerated dose, which is about three times that used here.

A more detailed account of these and other studies on plutonium detoxification will be published elsewhere. I am grateful to B. D. Chubb and the other assistants of the Metabolism Operation for their help on these experiments. The diethylenetriamine pentaacetic acid was supplied through the courtesy of the Geigy Chemical Corporation, Ardsley, New York. This work was performed under Contract No. *W*-31-109-*Eng*-52 between the Atomic Energy Commission and the General Electric Company.

Molecular Weight of Condensed Tannins as a Factor determining their Affinity for Collagen

EXAMINATION of the chemical principles of vegetable tanning[1] has led to various considerations of the nature of the bonds between tannin and collagen; to an examination of the possible 'active sites' of tannin fixation on the collagen chain, and to the quantitative study of tannin uptake in relation to the swelling of collagen[2]. The critical function of the different tannins normally present in any extract mixture in determining the quantitative and qualitative aspects of tannin affinity for collagen[3] was, however, largely overlooked in work emphasizing those important aspects listed above.

From a study of the relation between chromatographic behaviour and average molecular weight of 'condensed' tannin fractions, Evelyn and I (unpublished work) have recently found that in aqueous medium a gradational increase in molecular weight with decrease of R_F occurs over the ranges 550–3,200 for black wattle bark tannins (*Acacia mollissima*) and 790–2,350 for quebracho heartwood tannins (*Schinopsis* spp.). Similar behaviour also occurs in the 'partitioning' mixture *n*-butanol/acetic acid/water (6 : 1 : 2). We find, both under conditions of 'adsorption' and 'partition', that a linear relation exists between the average molecular weight of these typical 'condensed' tannin fractions and their R_M $\left(\text{defined as } \log\left(\frac{1}{R_F} - 1\right)\right)$ values.

I previously directed attention[3] to the parallel between the chromatographic behaviour of wattle tannin constituents on collagen columns and on paper chromatograms. These constituents also show the same relative affinities for various modified collagen substrates as for cellulose[4]. This similarity of behaviour of condensed tannins towards such widely differing substrates is further reflected in the low chromatographic affinities of catechins, flavan-3 : 4-diols (monomeric leuco-anthocyanins) and wattle 'polyphenolic non-tannins' for both collagen and cellulose, and also in the parallel increase in relative affinity resulting from the atmospheric oxidation of these substances[5]. This indicates the predominant effect of the nature of the tannins in determining their relative affinities for any substrate, in much the same way as the constitution of closely related dyes determines their affinity for cellulose and other natural materials[1,7].

The almost exact parallel between the relative affinities in aqueous medium (as reflected by 'adsorption' chromatographic behaviour) of condensed tannin constituents for cellulose, collagen and modified collagens, and the linear relation between their R_M values on cellulose and their average molecular weights, suggest that a similar relationship also exists between the R_M values on collagen columns and molecular weight. This has been partly confirmed by Evelyn (unpublished work), who established a direct relation between the average molecular weight of wattle tannin fractions and the proportion of 'irreversibly fixed' tannins in leather tanned with these fractions. Page[8] has also shown that the stoichiometric relationship of the combination of gelatin with various wattle tannin fractions (obtained by fractional precipitation from aqueous solution with salt) varies from the least soluble to the most soluble fractions. The gradational decrease in the 'gelatin number' he surmised to be due to a decrease in the molecular weight of the tannins and, in relation to our more recent findings, it also emphasizes the importance of the tannins in determining the 'affinity' between tannin and collagen. Peters and Sumner[7] found a correlation between the molecular weight of aminoanthaquinones and their chemical affinities for cellulose. The lower affinity of monomeric leuco-anthocyanins and catechins (phenolic 'non-tannins'), compared with that of naturally occurring complex leuco-anthocyanins[9] and polymeric catechins[10] ('tannins'), for hide powder during estimation of tannin appears to be due to the low molecular weight of the former (±300) in comparison with the latter (550–3,200). Following atmospheric oxidation, other factors, for example, the presence of quinonoid groups, increase their affinity.

The relation between R_M and molecular weight suggests the operation of physical forces between tannins and cellulose or collagen. This appears to be in line with the increasing emphasis on the importance of van der Waals forces between cellulose and various solutes, such as dyes[7,11]. Tannin mechanisms are, however, exceptionally complex, and hydrogen-bond forces undoubtedly play an important part[13] in the swelling of the hide, in the sorption and de-sorption of tannins, and possibly also in their fixation to collagen.

On the basis of the above work, it has been found possible to use paper chromatography as a method of interpreting the relative affinities of wattle and quebracho tannins for collagen. Planar 'flavonoid' compounds, for example, flavones, flavanols, anthocyanidins, aurones and chalkones[3,12], are exceptions, due to their abnormally high affinity for cellulose in aqueous medium.

Gas Chromatographic Separation of *Meta*- and *Para*-Xylenes in Aromatic Mixtures

THE xylene isomers have resisted all previous attempts at resolution by gas-liquid chromatography. An approach to their separation was made recently by Scott and Cheshire[1], who used a column with a calculated efficiency of 12,000 theoretical plates. Indeed, the chromatogram showed a very slight separation for *meta*- and *para*-xylene.

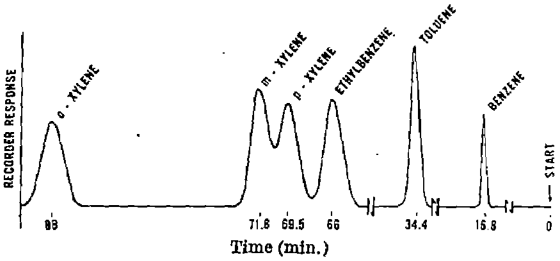

Fig. 1. Chromatogram of mixture of aromatics

The work reported here makes use of an aromatic hydrocarbon as the stationary liquid for effecting this difficult separation. Fig. 1 shows the resolution of a mixture of benzene, toluene, ethylbenzene, *ortho*-xylene, *meta*-xylene and *para*-xylene. Conditions for the separation were as follows:

Instrument	'Model 188' vapour fractometer
Column dimensions	5 m. × 5 mm.
Column temperature	100° C.
Stationary liquid	15 per cent w/w benzyldiphenyl (May and Baker Co.)
Column support	60–80 mesh 'Chromosorb' (Johns-Manville Co.)
Carrier gas	Helium
Carrier gas inlet pressure	59 lb./in.^{2}
Carrier gas flow	100 cm.^{3}/min.
Sample charge	0·005 ml.
No. of theoretical plates	9,500
Time of analysis	93 min.

The specificity of benzyldiphenyl and the high pressure-drop across the column permit the accomplishment of this separation in a reasonable time with columns of standard length and high efficiency. Sample sizes should, of course, be minimized.

Crystal Structure of Chabazite, a Molecular Sieve

THE 'molecular-sieve' properties of chabazite, a zeolite occurring in basaltic rocks, have been studied extensively. Molecules such as argon (diameter 3·84 A.) and methane (4·25 A.) are rapidly sorbed in the dehydrated zeolite; propane (width 4·9 A.) and *n*-butane are slowly sorbed, while *iso*-butane (5·6 A.) is excluded. A crystal structure was proposed by Wyart[1] in 1933, which consists of a three-dimensional framework of four- and six-membered rings of $(Si,Al)O_4$ tetrahedra (Fig. 1*a*). The rings form two cages per unit cell, the cages sharing six-membered rings which provide apertures of maximum dimension

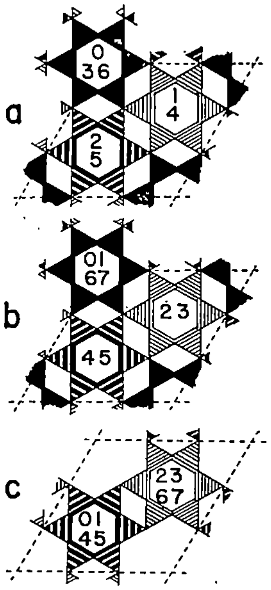

Fig. 1. Diagram to show stacking of six-membered rings of (Si,Al)O_4 tetrahedra in (*a*) Wyart's structure for chabazite, (*b*) the new structure for chabazite, (*c*) gmelinite. Different shading of the rings indicates different heights and the numerals represent the heights of the rings in which they occur, expressed as multiples of 2·5 A. In (*b*) and (*c*) each six-membered ring is linked directly to one immediately above or below it, forming hexagonal prisms. In (*a*) all linkages go outwards from the ring and hexagonal prisms are not formed. All the arrangements are idealized, especially in (*a*)

2·9 A. if the usual Si—O and Al—O distances are used, and 3·1 A. if the somewhat unusual distances in Wyart's structure are adopted. Although Kington and Laing[2] have interpreted the sorptive properties of chabazite in terms of Wyart's structure, the agreement can scarcely be regarded as satisfactory when a molecule of minimum dimension 4·25 A. passes easily through an aperture of diameter 2·9–3·1 A. As the structure of chabazite was proposed in the early days of crystal structure determination further investigation appeared desirable.

Using Fourier methods, a new structure has been determined which explains the X-ray intensities, the sorption and epitaxial intergrowth with the mineral gmelinite. The chabazite specimen contains two units of $(Ca_{0\cdot90}Na_{0\cdot15})$ $(Si_{4\cdot05}Al_{1\cdot95})_6O_{12}\cdot 6H_2O$ in a trigonal cell of symmetry $R\,\bar{3}m$ (or nearly so) and $a = 9\cdot40$ A., $\alpha = 94°\ 18'$. The positions of the silicon, aluminium and oxygen atoms are approximately:

Si,Al	0·34,	0·11,	−0·12
O_1	0·27,	−0·27,	0·00
O_2	0·17,	−0·17,	0·50
O_3	0·25,	0·25,	0·90
O_4	0·03,	0·03,	0·35

At the present stage of refinement, the distances (Si, Al)—O range from 1·63 to 1·68 A. and the O—O distances from 2·62 to 2·82 A., in excellent agreement with the standard values. From the positions of the silicon and aluminium atoms shown in Fig. 2 the nature of the framework may be seen. The new structure is built up of double six-membered rings (Fig. 1*b*) forming one 'cage' per unit cell. Each cage has six octagonal, two hexagonal and twelve quadrilateral faces, and is connected to the six neighbouring cages by eight-membered rings, permitting sorption in all directions, but limiting it by the octagonal (non-planar) apertures of minimum width about 3·9 A. Although the present work is being carried out on a hydrated specimen and the cavities are filled with water molecules and calcium ions, the framework is expected to differ only slightly in the dehydrated state and the size of the aperture should not change by more than 0·2 A. When thermal vibration is considered, the new structure gives an excellent explanation of the observed sorptive properties. The co-ordinates of all the atoms are being refined by successive Fourier series, and results for a dehydrated chabazite held at 300° C. in a stream of nitrogen are being collected in order to determine the movements of the framework and the calcium atoms as a result of dehydration.

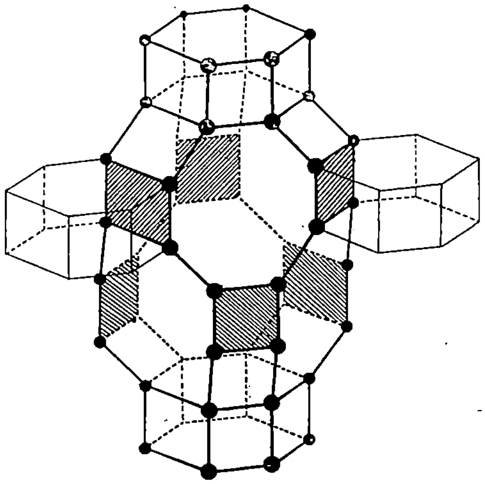

Fig. 2. The positions of the Si,Al atoms in chabazite. Shaded quadrilaterals represent points of attachment of hexagonal prisms, four of which are shown

Further confirmation of the validity of the structure arises from the ready interpretation that may be placed on the chabazite-gmelinite intergrowths. It has been pointed out[3] that not only are the hexagonal *a*-axes of the two minerals identical and the *c*-axes in the ratio of 3 : 2 but also that the two form oriented intergrowths, with streaks parallel to *c* joining the reflexions. The *c*-axis projection of gmelinite has been determined by O'Daniel and Fischer[4] and idealized in Fig. 1*c*. The *z* co-ordinates were not given, but it seems likely that they are as shown. The relationship of the stacking of the double rings in chabazite and gmelinite would be of cubic to hexagonal close-packing, and the intergrowths and diffuse streaks would be the result of stacking faults.

Such a structure for gmelinite would have channels the narrowest parts of which were twelve-membered rings, and it would be expected that gmelinite would sorb some *iso*-paraffins and aromatics. Barrer[5], however, reports that its sorptive properties are similar to those of chabazite, which excludes *iso*-paraffins and aromatics. One possible explanation of this anomaly is that Barrer's specimen (for which no X-ray data or locality were given) may have contained intergrown chabazite, or have been somewhat disordered; for either of which, sorption would be mainly limited by the eight-membered rings of chabazite. A second possibility is that the sodium ions of gmelinite may partially block the apertures, reducing the effective channel to the size of that in chabazite.

We wish to thank Dr. D. W. Breck, of the Linde Products Co., for helpful advice, and Prof. Ray Pepinsky and Drs. C. L. Christ and H. T. Evans,

Similarities in the Characteristics of Solar Radiation at λ 10·7 cm. and in the Far Ultra-violet

Denisse and Kundu[1] have directed attention to the close relation between the variations of two indices of the solar cycle which represent the flux of two different types of solar radiation. The first index ($Ch_E = f^4 \sec \chi$) is based on the monthly mean critical frequency (f) of the E-layer at noon at Freiburg (Germany); it is assumed to be proportional to the flux of the ultra-violet and X-radiation of solar origin which is responsible for the atmospheric ionization at heights near 120 km. The second index is the monthly mean value (Φ) of the solar radio-noise flux at λ 10·7 cm., measured at Ottawa, which is available from February 1947 onwards. Denisse and Kundu conclude that the two types of radiation are produced, if not by the same mechanism, at least under closely correlated conditions.

We have recently examined the characteristics of a number of indices of solar activity including both Ch_E, calculated using E-layer data for Slough (England), and Φ. We have confirmed that the correlation between the two indices is high ($r = 0{\cdot}90$), but we have also found that it is even higher if the data for each month are considered separately ($r_{\max.} = 0{\cdot}99$).

From Table 1, it can be seen that r is greater than 0·90, the value for all months taken together, in eleven out of twelve months. It may be inferred from this result that the correlation coefficient for individual months is significantly greater than that for all months considered together; the probability that the observed result occurred by chance is 3×10^{-3}.

The reason for the result just mentioned is that although the magnitude of Ch_E is controlled mainly by the flux of ionizing radiation, it also contains a small complicated seasonal component. For this reason, uncorrected values of Ch_E ought not to be assumed to be accurately proportional to the flux of the incident radiation. The seasonal component varies in amplitude with the level of solar activity, but a method of eliminating it has been devised and will be described elsewhere.

Table 1. CORRELATION COEFFICIENT (r) BETWEEN Ch_E (SLOUGH) AND Φ (OTTAWA). FEBRUARY 1947–DECEMBER 1956

Month	r
January	0·99
February	0·95
March	0·87
April	0·93
May	0·95
June	0·93
July	0·98
August	0·91
September	0·97
October	0·96
November	0·97
December	0·99
All months	0·90

A further similarity between the characteristics of the ionizing radiation and radio noise at λ 10·7 cm. is evident if the non-uniformity in the brightness of the Sun's disk at the two wave-lengths is studied when the disk is undisturbed. Such a study was possible during the eclipse of June 1954, when the Sun was unusually quiet and there were no localized active areas on the disk. During this eclipse, ionospheric measurements were made in the United Kingdom[2] and in Norway[3], and radio-noise measurements were made in Canada[4]. From these results it has been possible to make estimates of the relative brightness of the disk near the poles and near the east and west limbs, and the agreement between the ionospheric and the radio-noise results is quite striking[5] (Table 2).

Table 2. RELATIVE BRIGHTNESS OF THE EAST LIMB OF THE SUN AND THE POLAR REGIONS REFERRED TO THE CENTRE OF DISK (JUNE 30, 1954)

Type of measurement	East limb	Poles
Ionosphere ($F1$ layer)	1·8	0·86
Radio-noise (λ 10·7 cm.)	1·5	0·91

The results summarized in Tables 1 and 2 appear to confirm the conclusion reached by Denisse and Kundu; but it is probably premature to speculate on the precise reasons for the observed similarities in the characteristics of the two types of radiation.

This work was carried out as part of the programme of the Radio Research Board, and this communication is published by permission of the Director of Radio Research of the Department of Scientific and Industrial Research.

'Whistlers' in the Antarctic

'WHISTLERS' are being heard consistently at Scott Base, the New Zealand International Geophysical Year Antarctic Station, McMurdo Sound. From the time observations commenced on April 15 until the time of writing considerable activity has been observed, including 'bonks', 'tweeks', short and long 'whistlers', whistler trains, and periods of strong 'sferics'. No dawn chorus has yet been observed.

The geomagnetic co-ordinates of Scott Base are 79° 15′ S., 294° 30′ E. The base is located approximately 1,200 km. north-east of the geomagnetic pole and approximately 1,250 km. south-east of the dip pole. It is believed that this is the first time that whistlers have been heard in such a high geomagnetic latitude.

The whistlers appear to have dispersion characteristics similar to those heard in lower geomagnetic latitudes. However, the characteristics cannot be truly determined until tape recordings of them are sent to New Zealand for spectrographic analysis, at the end of the Antarctic winter.

Maximum activity occurred on April 15, 16, 19, 20 and 23. No consistent diurnal variation in activity has been noted. On all occasions of strong whistler activity the local geomagnetic activity has been moderate or quiet and the ionosphere undisturbed. During an intense auroral display no activity was heard, nor has any correlation been observed with visible meteor showers.

It seems most improbable that the whistlers heard here are propagated along the dipole field passing through Scott Base, as the lines of force in this case would extend to 24 Earth radii above the magnetic equator, and the gyro-frequency would be in the vicinity of 100 c./s.

Distortion of the dipole field by a strong equatorial ring current could possibly allow whistler propagation along lines of force between conjugate points in high geomagnetic latitudes. This hypothesis, however, does not seem tenable when it is considered that periods of maximum whistler activity at Scott Base have so far occurred during quiet magnetic conditions.

There is no record of lightning discharges being observed in high polar latitudes, and it seems improbable that these could occur as there is insufficient thermal radiation from the Sun to produce the necessary air movements. In these regions there appear to be no natural phenomena capable of initiating whistlers.

During the period that whistlers and 'sferics' have been heard an intense and electrically active low-pressure area has existed some 3,000 km. north of Scott Base. Many of the noises heard could undoubtedly have originated in this area. It is probable that the whistlers heard at Scott Base are propagated from lower latitude regions, first along the appropriate magnetic flux line, and then by reflexion from the lower ionosphere.

Visibility of Noise on Television Pictures

In investigations of the visibility of random noise in television pictures[1,2], it has been found that for narrow-band noise which is just visible the required noise power increases by about 20 db. as the centre frequency is raised from 0·15 to 2 Mc./s. For frequencies between 2 and 3 Mc./s., the noise power remains nearly constant[1], or shows a small fall[2]. It has been suggested[1] that this may be because of the generation of intermodulation products of low-frequency noise, due to the non-linearity of the voltage/brightness characteristic of the television tube. These low-frequency products should be much easier to see than the original high-frequency noise. It follows that the non-linearity should also affect visibility of noise if a sinusoidal signal, together with noise, is applied to the tube control-grid. In this case, sum and difference frequencies of the signal and noise should be produced. An experiment which appears to demonstrate the expected intermodulation effect has been carried out.

A normal television raster was displayed on the tube of a television monitor, the monitor being adjusted so that zero-level signal at the video amplifier input, that is, 0·7-V. double-amplitude peak, produced a brightness excursion between subjective black and peak white. A sinusoidal signal and random noise were then applied at the video amplifier input. The root-mean-square level of the noise, set at −40 db., was obtained by subtraction of 17 db. from oscilloscope measurement of the quasi peak-to-peak level[1] relative to 0·7-V. double-amplitude peak. This noise-level was quite low, but fairly representative for television. The noise band had a sharp top-cut at 3 Mc./s., and extended down to about 50 c./s. The noise was either 'white' (uniform power distribution over the frequency band) or 'quasi-triangular' (power per unit band-width increasing with frequency). The following results were practically independent of tube brightness setting. The visibility of 'white' noise appeared to be unaffected by presence of the sinusoidal signal, although the signal was increased to zero-level, and the frequency varied between 0·1 and 3 Mc./s. However, application of a sinusoidal signal of small amplitude drastically increased the visibility of 'quasi-triangular' noise. Visibility of noise increased with signal-level and, for a fixed level, maximum visibility occurred at a particular signal frequency f_s. This frequency was between 2·5 and 2·9 Mc./s., and increased as the noise spectrum was increasingly peaked at the higher frequencies. As the signal frequency was shifted towards f_s, from either above or below, the noise became progressively coarser in appearance. This was presumably because the approach of f_s to the mean 'carrier' frequency of the noise tended to give the noise envelope as the difference intermodulation product. For the 'quasi-triangular' noise spectrum of Fig. 1, an appreciable increase in visibility of noise was produced by application of a −40 db. signal, f_s being 2·9 Mc./s.

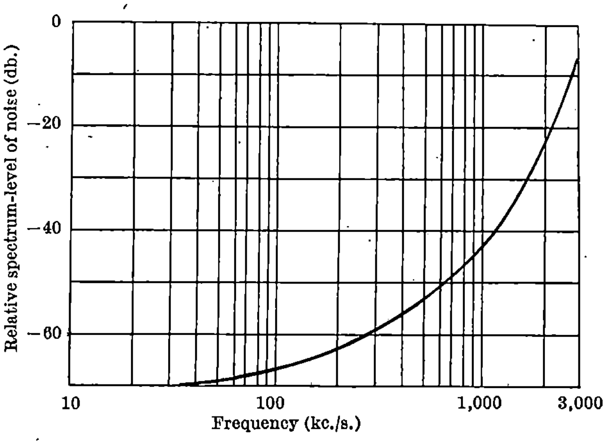

Fig. 1

Further details of this experiment, and others concerned with the effect of non-linearity on noise in television, will be published elsewhere. I wish to thank the Director of Engineering of the British Broadcasting Corporation for permission to publish this communication, and the head of the Designs Department under whose direction the work was carried out.

Repetitive Stimulation of Muscle

During a study of the effects of repetitive stimulation on the intracellular electrical activity of frog sartorius muscle fibres, alterations were noticed in the voltages of the second and subsequent spikes. At the same time, there was a progressive decrease in $t_{1/2}$ after-potential following the second and following spikes. All the experiments were performed on the green frog *Hyla coerulea* at a temperature of 22° C.

In preliminary experiments, the frequency of stimulation was increased from 10/sec. to 330/sec., which was the maximum frequency the muscle would follow on indirect stimulation. Up to a frequency of approximately 140/sec., spike voltage and duration remained of normal dimensions, and the $t_{1/2}$ after-potential was not appreciably altered after multiple spikes. Above this frequency, important changes were produced in spike voltages and durations, and $t_{1/2}$ after-potential. Fig. 1 shows the records obtained in a single muscle fibre with a progressively increasing number of stimuli at a frequency of 200/sec. A single muscle spike is followed by a negative after-potential of 13–17 mV., with a $t_{1/2}$ value of 13–18 m.sec. A second impulse 5 m.sec. later causes a reduction in the spike voltage, an increase in spike duration, and a shortening of the after-potential. As the number of spikes is increased, spike voltage decreases further until approximately the sixth spike, when a constant voltage is maintained for following spikes. At the same time, $t_{1/2}$ after-potential decreases until it reaches 6 m.sec., in this record, after the eleventh spike. Generally, once a $t_{1/2}$ of 6 m.sec. had been reached, no more spikes could be elicited. These results were repeated in many fibres, and all showed the same general trend of reduction in spike voltage and $t_{1/2}$ after-potential to limiting values which were constant for each muscle studied. Voltage of the negative after-potential did not appreciably alter as the number of stimuli was increased.

Experimental procedures which altered the $t_{1/2}$ after-potential, such as varying external concentrations of potassium, sodium and calcium ions, decreased or increased the number of spikes necessary to produce a $t_{1/2}$ of 6 m.sec. In all experimental conditions, a $t_{1/2}$ value of 6 m.sec. was reached.

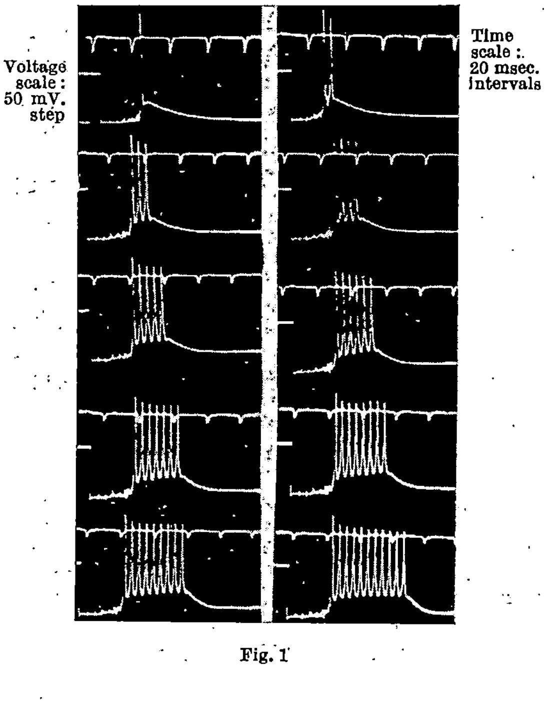

Fig. 1

It is thought that the progressive shortening of the after-potential is due to an accumulation of potassium ions immediately outside the muscle fibres.

Publication of details of this work will follow after these preliminary observations have been more fully studied.

Electrical Responses of Neuron Cell-Bodies in Sodium-free Media

The electrical activity of frog spinal ganglion cells is maintained, and even enhanced, when the external sodium has been totally replaced by equimolar amounts of either choline or tetraethylammonium[1]. Further investigations suggested that quaternary ammonium ions do not actually substitute for sodium as carriers of the action current, but probably exert a pharmacological action on the membrane or in the perikaryon[2].

A new series of experiments were performed to assess the effects on frog spinal ganglion cells of other related compounds which maintain the excitability of frog nerve fibres[3] or crab muscle fibres[4] deficient in sodium. The various solutions used contained, in addition to the amount of the drug tested, 1·8 m*M* calcium, 2 m*M* potassium, and sucrose to make up isotonicity (*p*H 6·4–7·0).

Sodium-free 112 m*M* solutions of tetramethylammonium, diethanol-dimethylammonium and acetylcholine chlorides had effects similar to those of a 112 m*M* choline chloride solution. A sodium-free 5–10 m*M* solution of tetrabutylammonium chloride maintained the excitability of a number of cells, but higher concentrations irreversibly depolarized and blocked them. A sodium-free 112 m*M* solution of ammonium chloride (*p*H adjusted to 7·0) exerted a powerful depolarizing action on the cells, but overshooting and prolonged electrical responses were obtained with 25 m*M*, although the resting potential still had a low value. A sodium-free 112 m*M* solution of guanidine hydrochloride maintained the excitability of the cells though the latter were slightly depolarized in this medium. A sodium-free 112 m*M* solution of hydrazine (*p*H adjusted to 6·4) had a very characteristic effect on the cell-body, as compared with the other onium ions. The configuration of the action potentials obtained in this medium was practically indistinguishable from that of responses in normal Ringer. Action potentials could be evoked by 'direct' and also by 'indirect' (that is, by propagated nerve impulses) stimulation.

With the exception of hydrazinium ion, the various active onium ions used in sodium-free solutions produced action potentials with a characteristic configuration (namely, peak, plateau, slow falling-phase), different from the 'normal' brief spikes recorded in Ringer's solution. The duration of the electrical responses, more than their peak height or rate of rise, was dependent on the kind and concentration of the drug applied. These prolonged action potentials might be considered as a particular, 'abnormal' manifestation of electrical activity induced by drugs. However, the striking similarity between 'hydrazinium spikes' and 'sodium spikes' suggests a single mechanism underlying the production of at least both brief responses, and apparently denies the exclusive necessity of external sodium for the generation of a 'normal' type of action potential in spinal ganglion cells. Moreover, it seems reasonable to assume that hydrazinium ion acts in the same way as the other onium ions, and it is not responsible for the actual transport of charge[2]. Electrical activity in the sodium-free media also seems unrelated to sodium entry, although the possibility of a partial retention of this ion in the extracellular spaces cannot be dismissed altogether. Calcium ions do not seem to play a direct part in the generation of electrical activity (Koketsu, K., Cerf, J. A., and Nishi, S., unpublished work). It could be suggested that hydrazinium and other onium ions condition the excitatory reaction and play an indirect part in the generation of electrical activity. The shape of the action potentials produced would depend on the ion species, however, and all intermediates can actually be recognized between the brief 'sodium' or 'hydrazinium spikes' and the prolonged 'tetraethylammonium' and 'tetrabutylammonium potentials'. It can be noted in this connexion that a moderate lengthening of the action potential, with appearance of a slight hump on the falling-phase, was occasionally observed in normal Ringer.

We wish to thank Dr. R. Lorente de Nó, of the Rockefeller Institute for Medical Research, for kindly supplying most of the drugs used in this study, and for his valuable suggestions.

Anomalous Bactericidal Action of Bromamine

As part of an investigation on the properties of the bromamines, their bactericidal efficiency was examined. These compounds are formed during the chlorination of sea water swimming pools in the presence of ammonia[1] and also in fresh water where bromine and not chlorine is used to sterilize the water.

Houghton[2] has made some studies of the bactericidal effects of solutions prepared by the action of chlorine on solutions containing ammonium salts and bromide ions, and found that these solutions were more efficient in destroying bacteria than were solutions containing only chloramine.

I have shown spectrophotometrically that solutions so prepared contain mainly monochloramine together with some monobromamine[1]. Experiments were accordingly made to determine the bactericidal effect of pure monobromamine relative to pure monochloramine.

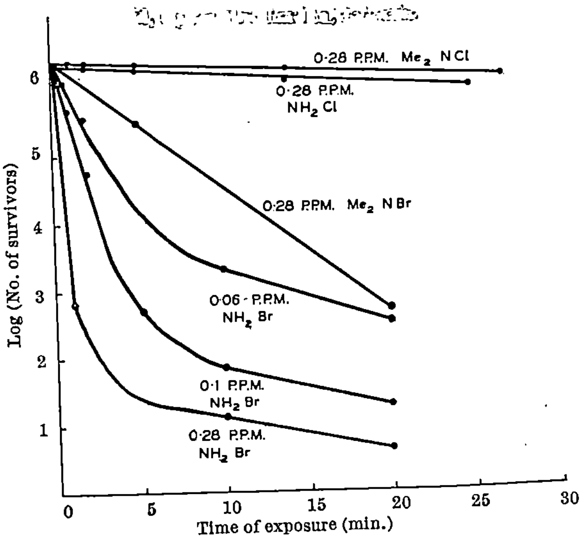

Fig. 1

Solutions of the amines were prepared by adding excess ammonium sulphate to solutions of hypochlorite for mono-chloramine, and to solutions of hypobromite for mono-bromamine. The solutions were buffered to approximately *p*H 8·2 with bicarbonate. 1-litre quantities of these solutions were treated with suspensions of *Escherichia coli* type 1, wild strain (from 18-hr. cultures that had been well washed), to give a cell density in the solutions of approximately 10^7/ml. Aliquots were taken after 1, 2, 5, 10 and 20 min. and pipetted into 0·5 per cent solution of sodium thiosulphate. The numbers of viable bacteria were then estimated by conventional plate counts and the results were plotted as the logarithm of the number of survivors against time.

For monochloramine the plot gave the expected linear relationship, but for monobromamine the curve showed a sharp break between 2 and 5 min., after which the rate became more linear and slower (Fig. 1). Amperometric determination of the halogen remaining after the experiments showed very little loss.

Unpublished work has shown that monobromamine reacts with dimethylamine even in the presence of a substantial excess of ammonium ion, and it was thought likely that a reaction of the type:

$$\text{(Bacterial)}\ -R_2NH + NH_2Br \rightarrow R_2NBr + NH_3 \quad (1)$$

took place. Accordingly, N-chlorodimethylamine and N-bromodimethylamine were prepared as described, substituting dimethylamine hydrochloride for the ammonium sulphate; and tested for their bactericidal action. For both the chloro- and the bromo-compounds the plot of the logarithm of the survivors against time was linear, the bromo-compound acting more rapidly than the chloro-compound.

The pK_a values of the monobromamine and monochloramine are respectively 6·5 (unpublished work) and 1·0 (ref. 3), and thus at the experimental *p*H value nearly 1 per cent of the bromo-compound is present as the monobromammonium ion (NH_3Br^+), which will have a strong tendency to react as follows:

$$NH_3Br^+ \rightarrow NH_3 + Br^+ \quad (2)$$

whereas monochloramine will have only an extremely small amount of the monochlorammonium ion (NH_3Cl^+) present: one part in 10^7 of the chloro-compound present.

The presence of this considerable amount of monobromammonium ion would account for the strong bactericidal properties of the bromo-compound, and further it would facilitate the exchange reactions as exemplified in reaction 1, the nitrogenous substances originating from the bacterial tissue.

Infectivity of Ribonucleic Acid from Mouse Brains infected with Semliki Forest Virus

EVIDENCE has been recently presented to show that the ribonucleic acids isolated by phenol extraction from tobacco mosaic virus[1], from ascites tumour cells in mice infected with Mengo encephalitis virus[2] and from mouse brains with Eastern equine encephalitis virus[3] are infectious. In the present communication, the infectivity of the ribonucleic acid isolated from the brains of mice infected with Semliki Forest virus is reported. This virus can also multiply in mosquitoes[4] but causes no known human disease.

Three-day-old Swiss mice were inoculated intracerebrally with 0·02 ml. of a 10^{-4} dilution of a homogenate of mouse brain infected with Semliki Forest virus. One day after infection, the brains were harvested, frozen in 'dry-ice'–ethanol and homogenized with 0·14 *M* sodium chloride–0·01 *M* sodium phosphate, *p*H 7·0, to give a 10 per cent homogenate. The supernatant is here designated as 'virus preparation'.

The ribonucleic acid was prepared by phenol extraction and precipitated twice with 65 per cent ethanol and once with 1 *M* sodium chloride following the procedures of Wecker and Schäfer[3]. The final precipitate was resuspended in phosphate buffer to a volume equal to that of the original mouse brain before dilution.

Infectivity titres, expressed as *LD*50, were determined by the intracerebral injection of serial 10-fold dilutions in mice, 0·02 ml. for one-day-old mice and 0·03 ml. for 30- to 40-day-old mice. The 10 per cent brain homogenate and the ribonucleic acid preparation were regarded as 10^{-1} and 10^0 dilutions respectively in calculating these titres.

The ribonucleic acid preparation exhibited about 0·1 per cent of the infectivity of the infected brain homogenate from which it was prepared (Table 1). The homogenate of the brains, harvested after infection with 10^{-3} dilution of the ribonucleic acid preparation, fixed complement with anti-Semliki Forest virus serum, an indication that the virus had multiplied in the recipient mice. Thus, the ribonucleic acid preparation contains all genetic information necessary for the production of complete Semliki Forest virus.

The ultra-violet absorption spectrum of the ribonucleic acid preparation was characteristic of nucleic acid, with a maximum at 257 mμ and a minimum at 230 mμ. The ratio between the optical densities was 2·1. Protein could not be detected by the biuret reaction. However, these results do not exclude the possibility that the infectivity might be due to small amounts of contaminating virus particles.

Table 1. COMPARISONS OF SEMLIKI FOREST VIRUS AND RIBONUCLEIC ACID PREPARATIONS

		Log *LD*50	
		Virus preparation	Ribonucleic acid preparation
A	No treatment	6·9	3·8
B	Control	5·5	3·7
	After ribonuclease 50 μgm./ml. 25° C.; 10 min.	5·6	*
	After deoxyribonuclease 50 μgm./ml. 25° C.; 10 min.		3·3
C	Control	3·6	1·9
	After centrifugation (top supernatant)	1·6; 1·6	1·3
D.	Control	6·0	3·5
	After sodium deoxycholate 0·1 per cent; 4° C.; 1 hr.	4·0	3·7
E	Control	4·1	2·3
	After sodium deoxycholate 0·1 per cent; 4° C.; 1 hr.	2·0	2·2

* No mice died at 10^0 dilution

In attributing the observed infectivity to the ribonucleic acid itself, rather than to contamination with intact virus, previous authors have relied on the differential effects of centrifugation and nuclease digestion on crude preparations of virus and ribonucleic acid[2,3] (cf. Table 1, *B* and *C*). In the present investigation, precautions were taken to make the two reaction systems reasonably comparable before repeating the differentiating procedures. The Semliki Forest virus was diluted ten-fold and centrifuged at 40,000*g*. for 1 hr. at 3° C. to remove extraneous tissue material, and the supernatant was diluted with the ribonucleic acid preparation to give an infectivity only one to two hundred times that of the ribonucleic acid system. The concentration of free ribonucleic acid was equal in the two systems.

As shown in Table 1, *B* and *C*, even under these conditions ribonuclease treatment did not reduce the infectivity of the virus preparation, presumably because the ribonucleic acid of the intact virus is protected by its protein coat. Furthermore, centrifugation sufficient to remove 99 per cent of the original infectivity of the Semliki Forest virus preparation reduced the infectivity of the purified ribonucleic acid by only 50 per cent.

In an effort to provide further evidence, the two preparations were exposed to the action of sodium deoxycholate, which has been shown to inactivate many of the arthropod-borne viruses[5]. 99 per cent of Semliki Forest virus was inactivated, but the infectivity of the ribonucleic acid preparation was not affected (Table 1, *D* and *E*).

These results, although not decisive, add to the now impressive body of evidence that the infective entity in ribonucleic acid preparations is ribonucleic acid itself and not a contaminating virus particle.

Protective Effect of Trace Elements other than Selenium against Dietary Necrotic Liver Degeneration

Rats fed on diets containing certain yeasts as their sole source of protein develop a dietary necrotic liver degeneration, leading to early and rapid death. Necrogenic diets are deficient in three factors, vitamin E [1], cystine [2] and a 'Factor 3' [3], each of which will alone prevent the manifestations of disease. Potent Factor 3 concentrates have been prepared from casein hydrolysates[4] and, recently, Schwarz and Foltz[5] have shown that similar concentrates prepared from kidney powder hydrolysates contain selenium in bound form. Addition of sodium selenite to rat diets (to supply 4 μgm. of selenium per 100 gm. of diet) gave complete protection against death from liver necrosis during the experimental period of thirty days, indicating that selenium might be part of Factor 3. Schwarz and Foltz have inferred that "selenium is an essential trace element".

We were prompted to investigate the addition of certain other trace elements to necrogenic diets, particularly those which, it was considered, might take part in oxidation-reduction mechanisms. Table 1 shows the results obtained by the addition of a number of trace elements at levels below their toxic levels (where these are known)[6]. Lead (alone) and a group of four metals, cerium, mercury, titanium and vanadium (together), were inactive. Molybdenum, osmium and cobalt (together) delayed the deaths by necrosis beyond 130 days in three rats out of seven. In the same test, the protective effect of selenium, cystine and α-tocopherol has been demonstrated. In a second test (Table 2), molybdenum, osmium and cobalt were given separately as well as in combination. Each of the three metals had some activity at the levels employed, but not all the animals receiving the supplement were protected. Further studies are in progress.

Table 1. Effect of Additions to the Neorogenic Diet*

Supplement	p.p.m.	No. of rats †		Remarks
		Total	Alive at 88 days	
Nil		6	0	
Sodium selenite	0·05	7	7	7 alive at 200 days
L-Cystine (0·6 per cent)		7	7	6 ,, ,, ,, ,,
DL-α-Tocopherol acetate (100 mgm./kgm.)		8	8	7 ,, ,, ,, ,,
Lead acetate	0·5	10	1	Survivor died at 89 days
Ammonium molybdate	0·5	7	3	Survivors died at 130, 154 and 170 days
Osmium tetroxide	1·0			
Cobalt sulphate	1·0			
Ceric sulphate	1·0	8	1	Killed. Liver normal
Mercuric chloride	1·0			
Titanous chloride	1·0			
Ammonium metavanadate	5·0			

* Basal diet (per cent): dried bakers' yeast, 30; vitamin E-free lard, 5; sucrose, 55; salts, 5; B vitamins in glucose, 5; vitamins A, D and K orally. The salt mixture contained the following trace elements: iodine, fluorine, copper, manganese and aluminium.

Heparin and Christmas Factor

Heparin has been shown to combine with Chargaff's[1] lung thromboplastin, which contains phospholipid. It inhibits the formation of intrinsic plasma thromboplastin[2], and Douglas[3] has shown that it must inhibit blood coagulation at an early stage. Heparin is also known[4] to combine specifically with the β-lipoproteins of plasma or serum and to depress the plasma β-lipoprotein concentration when injected *in vivo*. Christmas factor has been shown to be present in a crude α- and β-globulin fraction of plasma[5] and it may contain phospholipid[7].

A normal thromboplastin generation test was carried out using normal absorbed plasma, serum and platelets but with the prior addition of a suitable concentration (0·85 unit/ml.) of heparin. Little thromboplastin was formed. If the addition of heparin to the normal mixture is delayed until 3 min. after recalcification when the formation of thromboplastin is already maximal, the addition of heparin does not then affect the result; that is, maximal thromboplastin activity persists. Thus it is probable that heparin at this concentration prevents the formation of thromboplastin, but does not prevent its action once it is formed, and does not exhibit

Table 2. Effects of Molybdenum, Osmium and Cobalt

Supplement	Element (p.p.m.)	No. of rats	No. dying	Mean age at death (days)	Range (days)	Survivors at 100 days	Remarks*
Nil		10	9	60	42–92	1	Livers grossly necrotic
Ammonium molybdate	0·5	9	5	50	35–67	4	Post-necrotic scarring in two livers†
Osmium tetroxide	1·0	10	6	58	40–86	4	Livers normal
Cobalt sulphate	1·0	10	6	55	40–78	4	Post-necrotic scarring in one liver
Ammonium molybdate	0·5	9	5	55	37–84	4	Post-necrotic scarring in two livers
Osmium tetroxide	1·0						
Cobalt sulphate	1·0						

* Survivors killed and examined at 100 days.

† In all livers the scarring was confined to the left lobes and was accompanied by enlargement of the right central lobe.

any antithrombic activity in the sub-sample tubes.

Attempts to correct the defect produced by the addition of this critical amount of heparin showed that the addition of excess serum normalized the system. The addition of serum absorbed on alumina, which is deficient in Christmas factor and Factor VII, or the addition of serum from two cases of Christmas disease which is presumably deficient only in Christmas factor, both failed to do so. The addition of toluidine blue and protamine sulphate, both of which prevent the antithrombic activity of heparin, also failed to correct the defect.

A volunteer was given 2,500 units of heparin intravenously. 30 min. later blood was taken and it was found to have a long clotting time, but when mixed with normal plasma it did not prolong the clotting time of the normal plasma. Thus there was probably no free heparin in the volunteer's plasma at this time. In the thromboplastin generation test the volunteer's serum was shown to be abnormal, and this abnormality was corrected by the addition of normal serum diluted 1:10, but not by sera from two cases of Christmas disease similarly diluted. In these tests the volunteer's blood was therefore indistinguishable from that of a case of Christmas disease. It is concluded that heparin, *in vitro* and *in vivo*, may in some way interfere with the formation or the action of serum Christmas factor.

The apparently specific effect of heparin on Christmas factor was compatible with this factor being a lipoprotein. The lipoproteins of normal serum were separated by mixing serum with 20 per cent glycerin and centrifuging for 13 hr. at 170,000*g* in a preparative ultracentrifuge. The supernatant β-lipoprotein was removed and samples of this and the remainder were dialysed free of glycerol and tested in the thromboplastin generation test. The β-lipoprotein was inactive, while the remainder contained the full activity of the original serum. Thus Christmas factor is not in the β-lipoprotein fraction as isolated by this method.

It is concluded that the inhibition of the early stages of blood coagulation *in vitro* by heparin might be due to the action of heparin on Christmas factor. Since the intima of blood vessels may be lined by mucoitin, an acidic muco-polysaccharide like heparin, and since Christmas factor is involved at an early stage in blood coagulation, these tentative conclusions may be related to the inception of thrombosis *in vivo*. Further investigations are in progress.

This work was carried out during the tenure of a grant from the Medical Research Council, which I gratefully acknowledge.

Isolation of an Erythropoietic Fraction from the Plasma of Rabbits made severely Anæmic with Phenylhydrazine

The plasma of rabbits made severely anæmic with phenylhydrazine, with less than 3·7 gm. hæmoglobin per 100 ml. of blood, contains erythropoietic material. The erythropoietic activity has been demonstrated in heterologous species, for example, rats[1], mice[2] and dogs[3], in the filtrate obtained after boiling the anæmic rabbit plasma at *p*H 5·5 for a few minutes.

The following procedure has yielded a fraction which, on a protein basis, is 5–10 times more potent than the filtrate of the boiled anæmic plasma. The plasma proteins were precipitated at 5° C. at *p*H 6·0 by the addition of four volumes of saturated ammonium sulphate. The precipitate was extracted with 50 per cent saturated ammonium sulphate, and the soluble fraction was dialysed free of sulphate. Sodium chloride was added to the dialysand to 0·9 per cent, the *p*H of the solution was adjusted to 5·5, after which it was heated at 95–100° C. for 5 min., cooled quickly and filtered. The filtrate was concentrated by lyophilization to one-tenth its volume, dialysed until negative for chloride. The dialysand was concentrated further to a protein concentration of 2 per cent. Seven volumes of saturated ammonium sulphate solution were added to three volumes of the protein solution. The *p*H was brought to 6·0. After standing overnight at 5° C. the solution was filtered. The filtrate was dialysed free of sulphate and dried by lyophilization. 300 mgm. was obtained from 2·8 l. of anæmic plasma.

0·18 mgm. injected subcutaneously into mice daily for three days increased the reticulocytes from 2·1 to 10·2 per cent. 0·75 mgm. injected daily for three days into starved rats increased the uptake of injected iron-59 in the circulating blood to 22·6 per cent. 2·16 mgm. injected daily for two weeks into normal adult rats increased their hæmoglobin from 13·2 to 16·2 gm. per 100 ml. of blood.

When 750 μgm. of the dried material was submitted to electrophoresis on a strip of paper 30 mm. wide (veronal buffer, 0·05 *M*, *p*H 8·6) nearly all the protein material appeared as a broad band, which moved a little slower than serum albumin and faster than α_1-globulin, with a faint trace in the α_2-globulin region.

The dried material was submitted to moving boundary electrophoresis by the method of Mitchell and Herzenberg[4]. Two-thirds of the protein and all the demonstrable erythropoietic activity were in one band. Two faster-moving and one slower-moving bands had no demonstrable activity, and gave no augmented activity when added to the one active band.

On the basis of these and other experiments the following properties may be assigned to the erythropoietic principle. Erythropoietic activity so far has been inseparable from protein. Digestion with chymotrypsin or trypsin destroyed the activity. The active material is not dialysable, it is not lost after dialysis with 6 *M* urea, and it may be dried by lyophilization. It is stable to boiling at *p*H 5·5 for short periods. It is precipitated in the presence of all the plasma proteins by 80 per cent saturation with ammonium sulphate; the purified material in 0·6 per cent solution is soluble in 70 per cent saturated ammonium sulphate. Erythropoietic activity as measured by reticulocytosis in mice, increased uptake of iron-59 in rats and polycythæmia in rats went together in one electrophoretic fraction. Neither dialysis nor electrophoresis has separated a prosthetic group necessary for its activity. The active fraction gave a positive test for sialic acid[5] (mucoprotein).

Work is in progress on purification of the electrophoretic fraction.

Cytolipin *H*, a Pure Lipid Hapten isolated from Human Carcinoma

ANTISERA prepared by injecting rabbits with cytoplasmic fractions or homogenates of human tissues frequently contain antibodies directed against substances extractable from the tissue with organic solvents and presumably lipid in nature. Material derived from tumours is reported to be more effective than that from normal tissues in eliciting this type of antibody[1], suggesting that tumours may contain larger quantities of one or several lipoprotein antigens or possibly antigens qualitatively different. Exploration of this problem by the methods of immunochemical analysis is obstructed by several complications: the antigenic complexity of lipid extracts, the multiplicity of antibodies in the antiserum reagents, and the paucity of information regarding non-specific lipid–protein interactions for many classes of lipids. A fourth complication is of even greater moment than the other three combined, namely, the fact that specific lipid–protein interactions are markedly influenced by certain ubiquitous, non-specific lipids[2].

Analytical measurements can therefore shed only dim light on the problem of antigenic specificity and distribution until methods are developed which take into account the complex nature of the observed interactions. The development of such methods has, in turn, been hampered by lack of knowledge concerning the structure of lipid molecules which combine specifically with antibody as well as the absence of an adequate number of models for study. This communication reports the isolation from human carcinoma of a pure lipid hapten, its partial chemical characterization and its immunochemical properties. This substance, for which we propose the name 'cytolipin *H*', is a four-residue molecule the structure of which is capable of exact determination. It therefore offers a promising point of departure in attacking the complex problems associated with immunochemical studies of lipids.

The method of isolation was as follows: human epidermoid carcinoma (H.Ep. No. 3) grown in cortisonized rats was homogenized in a Waring blendor with 20 ml./gm. chloroform/methanol (2 : 1). The extract was washed with water according to Folch *et al.*[3], giving 2·5 gm. of a crude lipid soluble in chloroform per 100 gm. of wet tissue. The crude lipid was fractionated on silicic acid at 5° C. in 6 gm. lots using a discontinuous-gradient elution method with hexane and ethanol[4,5]. Fractions eluted with hexane and 5 per cent ethanol in hexane were rejected; the fractions emerging with 17 per cent ethanol in hexane were collected, yielding 30–90 mgm. per run, phosphorus 2–3 per cent, hexose (aminodiphenyl method[6]) 6–12 per cent. Material from ten runs was pooled to give 630 mgm., phosphorus 2·1 per cent, hexose 6·9 per cent. This was dissolved in 5 ml. of ethyl ether and 10 ml. of ethanol at 60°. A small quantity of insoluble material was rejected. On chilling, 171 mgm. was deposited, hexose 18·5 per cent. An additional 90 mgm. was obtained by adding 15 ml. of ethanol and 4 ml. of water, hexose 19·9 per cent. The supernatant, containing 376 mgm., phosphorus 2·49 per cent, hexose 2·7 per cent, was discarded. The fractionation was repeated to remove an additional 57 mgm. of soluble material, phosphorus 2·0 per cent, hexose 3·2 per cent, and the remaining phospholipid was removed by chromatography over 'Florisil' in chloroform/methanol (2 : 1)[7]. The yield was 80·9 mgm. of colourless material, phosphorus less than 0·02 per cent, hexose 36·5 per cent, nitrogen 1·47 per cent, which was recrystallized three times from hot pyridine/acetone (1 : 6) to give 63·8 mgm. having $[\alpha]_D^{24°} = -10{\cdot}8°$ (concentration 2 per cent in pyridine). Recrystallization from methanol/chloroform (9 : 1) did not affect the rotation.

This substance, cytolipin *H*, is insoluble in water and contains no ester groups or phosphorus. It is ninhydrin-negative, but on acid hydrolysis (3 *N* hydrochloric acid, 100°, 2 hr.), ninhydrin-positive material is released that is associated exclusively with a long-chain base (sphingosine). Hydrolysis also releases two molecules of hexose that migrate on paper (ethyl acetate/pyridine/water[8]) with the R_F values of glucose and galactose and appear in equal concentration. Evidence at hand suggests that cytolipin *H* is a cerebronyl–sphingosyl–glucosido–galactoside, but much additional structural work remains to be done. The composition is consistent with the formula $C_{54}H_{103}O_{14}N$ (molecular weight, 990·4); calculated: C, 65·49; H, 10·48; N, 1·41; hexose, 36·4 per cent; iodine No. 26; found: C, 65·46; H, 10·31; N, 1·38; hexose, 36·7 per cent; iodine No. 32.

Cytolipin *H* activity was followed by complement-fixation with rabbit anti-human reticulum cell sarcoma serum. The pure substance reacts very poorly in this test, but when combined with the optimal quantity of auxiliary lipid (a mixture of equal parts of lecithin and cholesterol), less than 0·001 μgm. can be readily determined. Under these conditions, cytolipin *H* reacts with rabbit antisera prepared by injecting many different types of human tumours. Isofixation curves[9] of cytolipin *H* with two rabbit anti-human tumour sera are shown in Fig. 1.

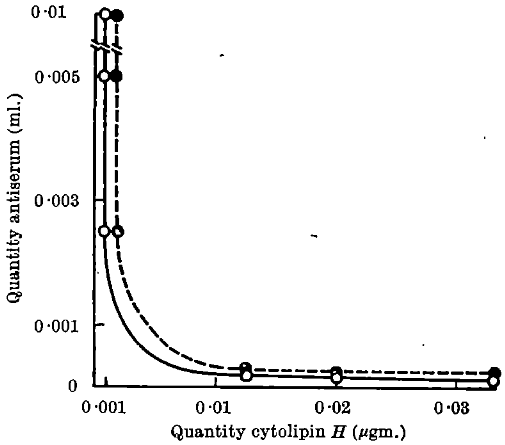

Fig. 1. Isofixation curves determined with cytolipin *H* and antisera to cervix carcinoma (broken line) and reticulum cell sarcoma (solid line). Three 50 per cent hæmolytic units (0·00375 ml. of guinea pig serum); 2 hr. incubation at 20° C. (ref. 9)

This work was supported by the American Cancer Society and a research grant (*C*-2316) from the National Cancer Institute of the U.S. National Institutes of Health, Public Health Service.

We wish to thank Dr. Morris Teller and his associates for supplying the tumour tissue and Richard Brandt for invaluable technical assistance. The carbon and hydrogen analyses were performed by the Spang Microanalytical Laboratory, Ann Arbor, Michigan.

Effect of Certain Polyphenylated Aliphatic Hydrocarbons on the Phagocytic Activity of the Reticulo-Endothelial System

In a recent communication to *Nature*, Nicol *et al.*[1] reported the effect of various stilbene compounds on the phagocytic activity of the reticulo-endothelial system, intimating that stimulation was associated with certain aspects in the chemical structure, and that the strongest stimulants possessed high œstrogenicity. The present communication reports the effect on reticulo-endothelial phagocytic activity of some polyphenylated aliphatic hydrocarbons related to the synthetic œstrogens of the diphenylmethane series.

The present experiments were carried out on 50 male white mice (*T.O.* Swiss strain) of 20–30 gm. body-weight. Five of the animals were used for assessing the effect of each compound on the phagocytic activity of the reticulo-endothelial system, each animal receiving one subcutaneous injection of 0·5 mgm. of each substance in 0·05 ml. of arachis oil daily for six days. The phagocytic activity of the reticulo-endothelial system was measured on the eighth day, as described in the previous communication[1].

Twenty-five animals were used as controls. Each received one subcutaneous injection of 0·05 ml. arachis oil daily for six days and then showed an average phagocytic index or *K* value of 13 ± 2·4.

Table 1. Effect of Certain Polyphenylated Aliphatic Hydrocarbons, containing at least one *para*-Hydroxyl Group, on the Phagocytic Activity of the Reticulo-Endothelial System

	Compound used	Phagocytic index (*K* value)	Œstrogenic activity (R.U.) (mgm.)
A	3 : 3-Di-(*p*-Hydroxyphenyl)-*n*-pentane	16 ± 2·2	5
B	3-(*p*-Hydroxyphenyl)-3-phenyl-*n*-pentane	11 ± 1·1	10
C	*p*-Hydroxyphenyldiphenyl-methane	13 ± 1·7	25
D	1-(*p*-Hydroxyphenyl-1 : 1-diphenylpropane)	10 ± 0·6	100 (inactive)
E	*p*-Hydroxyphenyltriphenyl-methane	8 ± 1·6	100 (inactive)
	Control values for 25 animals	13 ± 2·4	

Table 1 shows the relative *K* values of five polyphenylated aliphatic hydrocarbons investigated, together with their known levels of œstrogenicity. The results indicate that compound *E* has a profound depressant effect on phagocytosis only hitherto found following the administration of cortisone[2] in which the phagocytic index was reduced to *K* = 7. Compound *E* is the only non-steroid found by us to cause such marked depression of phagocytic activity. Compounds *B* and *D* show only a minor depressant action; compound *C* causes no alteration; while compound *A*, which is œstrogenic in the rat following doses of 5 mgm., has a slight stimulatory effect.

We are indebted to Prof. D. H. Hey for help in the interpretation of the above results and to Sir Charles Dodds for generously supplying these compounds. We also gratefully acknowledge assistance from the Central Research Fund of the University of London and from the Medical Research Council.

Species Difference in Pyridine Nucleotide Synthesis by Erythrocytes

Leder and Handler[1] have described the synthesis of pyridine nucleotide from nicotinamide and glucose by human erythrocyte homolysates in amounts as much as ten times the normal content and they identified the synthesized material as nicotinamide mononucleotide. These authors also suggested that fructose diphosphate and adenosine triphosphate

Table 1

Species	No. of observations	γ-Pyridine nucleotide (as diphosphopyridine nucleotide per c.c.):		Synthesis of pyridine nucleotide by erythrocytes from nicotinamide + glucose (γ-pyridine nucleotide formed/c.c. red blood cells)	γ Ribose/c.c. of whole blood	γ Ribose synthesized/c.c. red blood cells/hr.
		whole blood	erythrocytes			
Man	8	30·6	62·5	314·7	—	—
Monkey	6	63·1	145·0	nil	—	—
Rat	6	94·2	205·0	nil	186·0	82·3
Mouse	2	194·1	407·5	nil	—	—
Guinea pig	6	37·8	77·1	346·9	147·2	75·3
Rabbit	2	59·5	131·8	nil	—	—
Sheep	3	—	192·1	nil	—	—

were required for optimal synthesis of nicotinamide mononucleotide. While synthesis of pyridine nucleotide is thus known to occur *in vitro* by washed human erythrocytes, its presence and its synthesis in other mammalian species have not yet been examined.

In our recent studies on the metabolism of pyridine nucleotide it was observed that the washed red blood cells of the rat were unable to synthesize that substance under conditions similar to those employed by Leder and Handler[2] in human erythrocyte studies. This finding induced us to examine further the behaviour of different species of animals, namely, mouse, rat, guinea pig, rabbit, sheep, monkey and man, as regards synthesis of pyridine nucleotide by erythrocytes.

The total pyridine nucleotide content of the whole blood was estimated by the method of Levitas *et al.*[3]. The capacity of fresh erythrocytes, washed four times at 3° C. with four volumes of glucose–Ringer phosphate, *p*H 7·2, to synthesize nicotinamide mononucleotide was estimated by the method of Leder and Handler[2]. In some experiments with rats and mice, the incubation mixture contained fructose-1 : 6-diphosphate, adenosine triphosphate and D-ribose, in addition to nicotinamide and glucose.

The results presented in Table 1 demonstrate that, of the seven species studied, only man and guinea pig erythrocytes were capable of synthesizing pyridine nucleotide under the conditions of the experiment. However, all the species that were unable to synthesize it had a higher pyridine nucleotide content of blood than guinea pig or man. This suggests that the major site for synthesis of nicotinamide mononucleotide in these species may be a tissue other than blood.

Although it is uncertain whether the formation of nicotinamide mononucleotide in blood cells occurs by the direct phosphorylation of nicotinamide riboside by adenosine triphosphate as shown in liver preparations by Rowen and Kornberg[4], or by the reaction between the base and ribose-5-phosphate or 5-phosphoribosyl-1-pyrophosphate[5], it is reasonable to assume that the conversion of glucose-6-phosphate to ribose phosphate by way of a hexose monophosphate shunt may be an essential step in the synthesis of nicotinamide mononucleotide from nicotinamide and glucose. My results demonstrate that the formation of ribose phosphate from glucose-6-phosphate in rat and guinea pig erythrocytes, as well as the ribose content of the whole blood of these two species, were almost equal. It was evident, therefore, that the ribose phosphate did not seem to be a limiting factor in synthesis of pyridine nucleotide in rat erythrocytes. It is hoped that experiments with erythrocyte homolysates and liver preparations now in progress may provide some information regarding the comparative role of these tissues in synthesis of pyridine nucleotide in different species of animals.

Investigations into Temperature Changes on the Surface of Human Tooth Enamel

In one of the first observations made with the aid of the microscope, Leeuwenhoek[1,2] found that he could detect fewer organisms in scrapings taken from teeth after drinking hot fluids than in scrapings taken before the drink. Although many investigations have been made into the physical effect of thermal changes upon enamel and into the effects of conducted heat upon the dental pulp, there is no evidence in the literature of Leeuwenhoek's observation having been pursued.

In the present series of experiments, investigations are being carried out from the aspect of the effects of temperature changes upon chemical or bacterial activity taking place upon the surfaces of human teeth. To ascertain the range of such changes on enamel surfaces during meals, pilot experiments were performed using copper-constantan thermocouples attached to the surface of enamel and in areas between teeth. Meals were eaten at a serving temperature of 60–70° C., during which thermocouple readings were taken every 30 sec.

It was found that maximum temperatures of 50–60° C. were reached and temperatures of 40–45° C. were maintained for up to ten minutes at a time. In areas between the teeth, the temperature on the enamel surface took, on average, thirty minutes after the finish of the meal to return to 37° C.

When measuring surface temperatures it is necessary to know the thermal conductivity of the material the surface of which is under examination, and since only a rough estimate of the thermal conductivity of enamel has been made[3] it was thought that as a preliminary investigation the thermal conductivity of enamel should be determined. The apparatus in use for this is a modification of that used by Phillips, Johnson and Phillips[4] for the determination of the thermal conductivity of dentine and dental cements. Results indicate that the value of the thermal conductivity of enamel is of the order 0·002 c.g.s. units, and that variations occur with the age of the enamel. Since the value is in the same range as ceramic materials, thermistors will be more suitable for use on enamel surfaces than thermocouples. Experiments are being conducted with thermistors recording on to pen-recorders.

It would seem that if the detailed investigations confirm the indications of the pilot work, it may be incorrect to perform *in vitro* experiments into dental caries at 37° C. and regard them as being a reproduction of *in vivo* conditions.

Effect of the Nitrogen and Sulphur Content of Organic Matter on the Production of Ammonium and Sulphate

AT this Laboratory, investigations into the decomposition of soil organic matter have been concerned with the effect of sulphur and nitrogen content on decay. To simplify the problem in its preliminary stages, and to gain better control of variables, the decomposition of mixtures of pure organic substances was studied.

This communication reports the effect of varying the nitrogen and sulphur content of such 'organic matter' on production of ammonium and of sulphate.

Mixtures of sucrose, casein, glycine and cysteine were used to vary the nitrogen and sulphur content of the organic matter—the carbon content was kept constant. Solutions of mixtures of these compounds, together with an inorganic salt solution, were inoculated with a soil extract and 40 ml. was then added to 300 gm. of clean sand in a series of 500-ml. flasks. After placing a small tube of sodium hydroxide solution in the flasks, they were closed with a thin sheet of polyethylene and were incubated at 27° C. With the quantities of organic matter used, diffusion of oxygen through the polyethylene into the bottle was rapid enough to sustain respiration at a rapid and probably maximal rate. Absorption of the carbon dioxide by the sodium hydroxide was much more rapid than diffusion out through the polyethylene. (Negligible loss of carbon dioxide occurred even when it was evolved very rapidly by action of acid on carbonate.) On the other hand, the concentration of carbon dioxide in air is so low that diffusion into the bottle was very small and in any event could easily be measured by a blank determination. At each sampling two bottles per treatment were taken to determine the sulphate, ammonium and carbon dioxide produced (no nitrate was detected). This allowed calculation of the carbon, nitrogen, and sulphur remaining in the organic form—though this calculation is subject to error if losses occur by formation of volatile compounds. It was thus possible to follow changes in the ratios of organic carbon to organic nitrogen and of organic carbon to organic sulphur (carbon/nitrogen and carbon/sulphur ratios).

Formation of ammonium was sometimes considerably delayed. This only happened when the initial carbon/nitrogen ratio was wider than about 5/1 and was only well marked when there was at least one part of sulphur to every hundred parts of carbon. One such curve is shown in Fig. 1, treatment 1. Calculations showed that the upward trend in such curves never occurred until respiration had lowered the carbon/nitrogen ratio to about 5/1.

However, when the proportion of sulphur in the organic matter was reduced, ammonium was formed more rapidly and before the carbon/nitrogen ratio had fallen to 5/1. Fig. 1 shows release of ammonium from organic matter with an initial carbon/nitrogen ratio of 13·3/1 and initial carbon/sulphur ratios varying from 100/1 to 400/1. Release of ammonium from material of wide carbon/sulphur ratio occurred much more rapidly and at much wider carbon/nitrogen ratios—as wide as 12/1 for treatments 4 and 5. It would seem that utilization of nitrogen was limited by the supply of sulphur and that nitrogen in excess of microbial needs was mineralized.

The highly significant initial rise and subsequent fall in the curve for treatment 4 in Fig. 1 is worthy of note. On this treatment the micro-organisms apparently did not attack the organic compounds at the same rate: it would seem that the nitrogen-rich compound (in this case glycine) was attacked more rapidly than the energy-rich compound (sucrose) and excess nitrogen was mineralized. Later, presumably when the sucrose was fully utilized, some of this nitrogen was immobilized. A similar 'premature' formation of sulphate occurred in some other experiments, but in most cases the micro-organisms appeared to attack the simple organic compounds at the same rate.

Graphs of sulphate production against time—like those for ammonium production—sometimes showed a flat initial phase before production of sulphate occurred. The upward trend in the curves did not

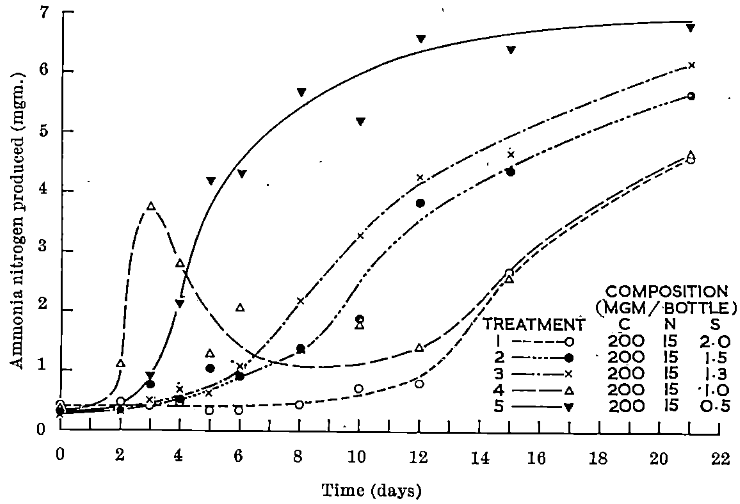

Fig. 1. Release of ammonium from mixtures of sucrose, glycine, and cysteine of the composition shown. The maximum value of the least range for significance (ref. 1) at $P < 0·01$ is 1·45 mgm. ammonia nitrogen

occur until respiration had lowered the carbon/sulphur ratio to about 50/1. When the proportion of nitrogen in the organic matter was reduced, production of sulphate tended to be more rapid—though the effect did not seem to be nearly as well marked as the effect of reducing the proportion of sulphur on production of ammonium.

These results suggest that mineralization of an element from organic matter depends not only on the proportion of that element in the organic matter but also on the proportion of the other elements. It is probable that a similar generalization applies to immobilization of elements, and in fact other results from these experiments have shown that immobilization of phosphorus was reduced when the proportion of nitrogen or of sulphur in the organic matter was reduced.

The statistical analysis was performed by Mr. P. F. May, of the Division of Mathematical Statistics, Commonwealth Scientific and Industrial Research Organization. It is intended to publish this work in greater detail elsewhere.

Absence of γ-Aminobutyric Acid from Brain Extracts containing Factor I

Florey[1] and Florey and McLennan[2,3] have described some of the actions of extracts of brain and spinal cord which possess an inhibitory activity on certain synaptic processes, both in mammals and in invertebrate animals. For example, these extracts, which are said to contain 'Factor I', can block transmission in sympathetic ganglia, can inhibit monosynaptic reflexes, can block neuromuscular transmission and the neurogenic heartbeat of Crustacea, and can inhibit the discharge of crustacean stretch receptor neurones. Bazemore, Elliott and Florey[4] have reported that an active component of extracts containing Factor I is γ-aminobutyric acid. Since that time it has been shown that γ-aminobutyric acid does have effects of an inhibitory nature, especially in Crustacea[5] and when applied to the mammalian cerebral cortex[6]. However, a comparison of the actions of Factor I and γ-aminobutyric acid on those structures where the former is active has shown that, except in Crustacea, the effects obtained with the two are not comparable, and it was concluded that they are not identical[7].

In the present experiments a solution of Factor I was applied to Whatman No. 4 filter paper, and subjected to chromatographic separation for free amino-acids. The solvents used were *n*-butanol/glacial acetic acid/water (4 : 1 : 5, v/v/v) in one dimension, and 80 per cent (w/w) aqueous phenol in the second. The chromatograms were developed with ninhydrin solution to reveal the amino-acid spots.

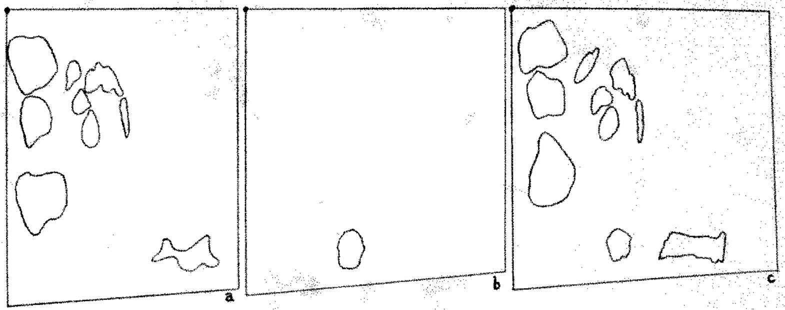

Fig. 1. Tracings of descending chromatograms developed with ninhydrin. In each case the solution was applied to the upper left-hand corner. The horizontal dimension represents movement in the butanol/acetic acid/water solvent, and the vertical the movement in phenol. (*a*) Factor I solution, 0·025 ml.; (*b*) γ-aminobutyric acid solution, 0·01 ml. of 1 mgm./ml.; (*c*) Factor I solution, 0·025 ml.; γ-aminobutyric acid solution, 0·01 ml.

Fig. 1*a* shows the distribution of spots obtained with a solution of Factor I prepared according to Florey and McLennan[2]. Fig. 1*b* shows the spot obtained when a solution of pure γ-aminobutyric acid was applied to the paper, and Fig. 1*c* the result when Factor I with added γ-aminobutyric acid was applied. It is evident from these chromatograms, which were all performed simultaneously, that there is no spot in Fig. 1*a* corresponding to γ-aminobutyric acid, such as appears clearly in Fig. 1*c*, where the substance was added artificially to the solution of Factor I.

It can be concluded from this experiment that extracts containing Factor I prepared by the method of Florey and McLennan, which possess the whole complex of actions described by those authors, contain no γ-aminobutyric acid, which cannot therefore be the active component of Factor I. Nor can it be argued that the quantity of Factor I applied to the paper in Fig. 1*a* contains an undetectably small amount of γ-aminobutyric acid, for the amount applied is 2½–5 times that required to block the crayfish stretch receptor neurone, and is therefore at least 2½ times more than the amount applied in Fig. 1*b*[7]. A possible explanation for the finding of Bazemore *et al.*[4] that γ-aminobutyric acid was present in the extracts containing Factor I is that it was split off from some larger molecule in the course of the relatively drastic extraction procedures which were used. It may perhaps be conjectured that this postulated larger molecule, of which γ-aminobutyric acid is a fragment, is the true active ingredient of Factor I solutions.

Composition of the Rous Virus Nucleoid

A TECHNIQUE, modified from that of Gessler, Bender and Parkinson[1], was recently devised to investigate the purifying effect of a fluorocarbon on vaccinia virus[2].

The technique has now been applied to nodules of Rous tumour grown on the chick chorio-allantois in order to prepare suspensions of the Rous virus. Such suspensions have been subjected to high-speed centrifugation and the pellets which resulted have been fixed, embedded, sectioned and examined in the electron microscope. It has been found that the only recognizable formed structures present in the pellets were uniform spherical particles about 75 mμ in diameter (Fig. 1), and biological tests integrated with the morphological work have established that these particles were in fact the Rous virus[3]. Fragments of the pellets containing the virus are ideal both for examination by electron and fluorescence microscopy after enzyme digestion, and for cytochemical study.

The nucleoid of the Rous virus is known to lie in a central zone separated from the viroplasm by a fine membrane[4]. In order to investigate the nature of the nucleoid, samples of the pellets containing the virus have been treated with ribonuclease. The samples were first fixed with potassium permanganate[5] which, unlike the more commonly used osmium–sucrose fixative for electron microscopy[6], allows subsequent digestion by both deoxyribonuclease[7] and, under certain conditions, ribonuclease. After fixation, the samples were placed in iced 30 per cent alcohol and allowed to warm to room temperature[5]; they were then incubated for 2 hr. at 37° C. in 30 per cent alcohol containing 0·1 per cent by weight of ribonuclease, protease-free, and recrystallized three times (Worthington Biochemical Corporation, Freehold, New Jersey). Control samples were incubated simultaneously in 30 per cent alcohol without the enzyme. After incubation, all the samples were dehydrated, embedded in *n*-butyl methacrylate and sectioned for examination in the electron microscope.

The incubation procedure made the particles appear ragged and extracted (Fig. 2). It is nevertheless clear that in the control preparations, which were not exposed to the ribonuclease, the nucleoid and outer limiting membrane remained intact (Fig. 2*a*). On the other hand, the nucleoids were removed from particles which had been subjected to ribonuclease digestion (Fig. 2*b*); such particles also appeared slightly swollen as if some central supporting structure had been removed. The specificity of the ribonuclease digestions in conjunction with the findings of the control experiments demonstrate that the nucleoid of the Rous virus contains a substantial amount of ribonucleic acid. This work will be reported in detail elsewhere[8] together with a discussion of its significance.

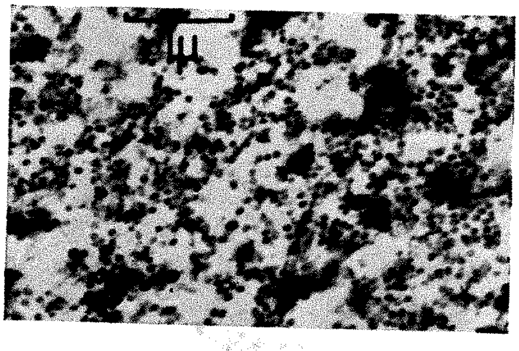

Fig. 1. Electron micrograph of a section through a pellet prepared from a suspension of the Rous virus which had been treated seven times with a fluorocarbon. Uniform virus particles about 70–75 mμ in diameter are almost the only formed structures present. Permanganate fixation. × 14,000

A Cobalt-Accumulator Plant, *Clethra barbinervis* Sieb. et Zucc.

DURING an investigation to determine if variations in the heavy-metal content of vegetation and soil could be used in prospecting for chromite ore bodies in the Hinokami district, Tottori Prefecture, a tree, *Clethra barbinervis* Sieb. et Zucc., was unexpectedly found to be an accumulator of cobalt.

Leaves of seventeen different kinds of trees collected from 199 locations in the neighbourhood of the mine were analysed for iron, nickel, cobalt, copper, zinc, manganese and chromium. The cobalt and nickel

Table 1. Cobalt, Nickel and Iron Content of Plant Leaves

Species	No. of samples	Average content (p.p.m. of ash) Co	Ni	Fe	Average ratios Ni/Co	Fe/Co
Clethra barbinervis Sieb. et Zucc.	17	661	140	548	0·38	1·37
Quercus crispula Blume	69	2·6	42·2	614	20·7	386
Deutzia crenata Sieb. et Zucc.	26	5·3	24·0	791	7·8	175
Castanea crenata Sieb. et Zucc.	24	3·6	31·8	846	11·1	243
Cynoxylon japonica Nakai	24	2·0	24·6	688	20·3	482
Lindera umbellata Thunberg	11	4·3	26·7	696	7·1	204
Other species	28	3·9	32·2	671	12·8	289

content of the ash of a variety of trees other than *Clethra* sp. ranged from less than 1·0 to 22·5 p.p.m. and from 3·2 to 120 p.p.m., respectively. More than one hundred times as much cobalt and several times as much nickel were found in *Clethra* sp. as in other plant species. Normally, plants contained from seven to twenty times more nickel than cobalt, but *Clethra* sp. contained more cobalt than nickel, although it was not richer in iron.

The total nickel content of the soil (*B*-horizon), which was mostly derived from serpentine parent material, ranged from less than 100 to 3,010 p.p.m. dry weight, the average being 1,005 p.p.m.; the total cobalt content also ranged from 10 to 9,250 p.p.m., the average being 652 p.p.m. The soil on which *Clethra* sp. was growing did not show any anomalous levels in these elements, yielding on average 1,125 p.p.m. of nickel and 511 p.p.m. of cobalt.

There is no evidence that cobalt is essential for higher plants, although certain species of lower plants and bacteria require this element. The large accumulation of cobalt in leaves of *Clethra* sp. suggests that this element may have some function in higher plants. Further work is proceeding and will be reported in detail elsewhere.

Morphology of Yeast Mitochondria

There has recently been some controversy as to the possibility of demonstrating other than granular mitochondria of yeast cells[1-3]. It is well known that for a long time the only mitochondria that cytologists were able to demonstrate in yeast cells were round, granular structures. As their minute dimensions make it practically impossible to observe the same cell before and after treatment with fixatives, stains, etc., the identification of yeast mitochondria must necessarily be doubtful. However, knowledge of the structure of the living cell, and the comparison of cytochemical results with the state of the living untreated cell, should be good safeguards against incorrect interpretation. One frequently abstains from using phase-contrast when examining yeast cells because, under the usual conditions of examination, cells of the yeast type which have a high solid content and refractive index give unsatisfactory images[4]. The fact that incomparably better results can be obtained with phase-contrast, provided immersion media of suitable refractive index are used, was stressed in Britain by Barer *et al.*[5], and this principle has been used by us for the study of micro-organisms, notably yeast cells.

From the cytochemical investigations of Ephrussi and his school[6], who used both normal and respiration-deficient strains of yeast, it can be concluded with certainty that in the case of yeasts a positive Janus green *B* reaction depends on the activity of the cytochrome *c* – cytochrome oxidase system. So far as is known, therefore, those structures of the yeast cell which, after careful treatment, can be stained with Janus green may be considered as mitochondria.

When Yotsuyanagi[1], using a double differential staining method, observed thread-like as well as granular structures in yeast cells and identified them as mitochondria, Williams *et al.*[2] denied the presence of long cylindrical mitochondrial threads in yeasts and emphasized that thread-like structures in such cells were only seen as artefacts after they had been stained with 2,3,5-triphenyltetrazolium.

The controversy between Williams *et al.*[2] and Ephrussi *et al.*[3] is solely based on what I believe to be Williams's incorrect interpretation of Yotsuyanagi's results. I should like to correct the statement of Williams *et al.* that "no other observer has ever reported long cylindrical cytoplasmic structures in *Saccharomyces*".

Quite independently of Yotsuyanagi's work, I have in recent years investigated the morphology and continuity of yeast mitochondria. According to my results, thread-like mitochondria seen in yeast cells are true structures of the living cell and not artefacts produced by the use of stains[7]. Using phase-contrast refractometry[8], I succeeded in demonstrating thread-like mitochondria in a number of yeast strains. This method so greatly facilitates their analysis that I was able some years ago to study their living structure by time-lapse microcinematography. One of my film-strips, which shows thread-like mitochondria during budding (*Sacch. carlsbergensis*) and cell-division (*Saccharomycodes ludwigii*) was shown at the meeting of the Research Film Section of the International Scientific Film Association in Göttingen in 1956. Fig. 1 shows the typical shape of thread-like mitochondria with negative phase-contrast. The interpretation of Williams *et al.* that such thread-like structures in yeast cells must be regarded as artefacts is thus refuted by the demonstration of thread-like mitochondria in living, untreated cells.

Provided special care is used, it is possible to stain these thread-like mitochondria with Janus green *B*.

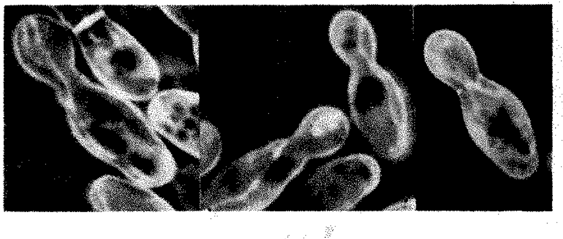

Fig. 1. *Saccharomycodes ludwigii*: long, thread-like mitochondria in living, unstained cells (*a* and *b*) and during cell-division (*c*). Negative phase-contrast, magnification, × 1,200; refractive index of the medium, 1·377

I could not, however—in contrast to Yotsuyanagi[1]—demonstrate them after fixation. My experience showed that thread-like yeast mitochondria are extremely sensitive to any type of interference with the cell, including vital staining and fixation. Great importance must therefore be attached to the analysis of their living structure. Fragments of thread-like mitochondria, as found, for example, after treating the cells with vital stains, may for a limited period remain stainable with Janus green. Their structure does not, however, correspond completely with what is found in the living cell.

Fluoroacetamide as a Systemic Insecticide

It has previously been reported that sodium fluoroacetate is a very effective systemic insecticide against *Aphis fabae* Scop.[1,2]. Unfortunately, its use cannot be recommended since it is a very dangerous poison, being both highly toxic and rapid in action.

As a result of the above report, related compounds have been investigated, and it has now been stated that fluoroacetamide is an active insecticide[3], although no details of biological tests have been published. Fluoroacetamide is claimed to be considerably less hazardous to handle than sodium fluoroacetate because it is less toxic and acts more slowly[4,5]. Furthermore, in rats acetamide acts as an antidote to fluoroacetamide but not to sodium fluoroacetate[5,6].

The biological tests were carried out as previously described[2,7]. The test insects were the bean aphis, *A. fabae* Scop., on broad beans, the cabbage aphis, *Brevicoryne brassicae* L., the peach potato aphis, *Myzus persicae* Sulz., on young cabbage plants and the eggs and larvæ of the large white butterfly, *Pieris brassicae* L., also on young cabbage plants.

In tests in which leaves bearing *A. fabae* and *B. brassicae* were dipped, fluoroacetamide was as effective as sodium fluoroacetate, 0·001 per cent solutions containing a wetting agent giving 100 per cent kill. Both were superior to schradan. When leaves bearing eggs of *P. brassicae* were similarly dipped in 0·1 per cent fluoroacetamide solution, 85 per cent of eggs failed to hatch and 70–80 per cent of the larvæ were killed. The same concentration of sodium fluoroacetate had no effect on the number of eggs hatching but killed 98 per cent of the newly emerged larvæ. Less than 10 per cent of the fourth instar larvæ were killed following immersion for 0·5 min. at 20° C. in the 0·1 per cent fluoroacetamide solution plus wetting agent.

When poured on to the soil, for systemic action against *A. fabae*, fluoroacetamide was as immediately effective and as persistent as sodium fluoroacetate: 2 mgm. (in 20 ml. solution) applied to 400 gm. of moist compost giving 100 per cent kill. It was therefore superior to schradan. When applied in the same way against *B. brassicae* and *M. persicae*, fluoroacetamide was superior to sodium fluoroacetate. The former aphid was killed by a dose of 0·2 mgm. and the latter by 1·0 mgm. of fluoroacetamide on the same weight of compost. Applied in this way, neither compound prevented the eggs of *P. brassicae* on the leaves of young cabbage plants from hatching, but all the young larvæ were killed by a dose of 10 mgm. fluoroacetamide or 20 mgm. of sodium fluoroacetate on the soil.

When administered to broad bean plants by the cut tap-root technique[2], the approximate *LD*100 in mgm. per kgm. of fresh plant tissue for *A. fabae* was fluoroacetamide 0·09–0·9, sodium fluoroacetate 0·7, schradan 50. When taken up through the petioles of the leaves of small cabbage plants 5 mgm. of the fluorine compounds or 50 mgm. schradan per kgm. of fresh plant tissue killed all *B. brassicae*. The growth of *P. brassicae* larvæ was prevented by 20 mgm./kgm. of either fluorine compound. For schradan more than 2,900 mgm./kgm. was required.

When applied to the older leaves against all three species of aphids feeding on the younger leaves of their host plants, fluoroacetamide was as effective as or slightly superior to sodium fluoroacetate as a systemic insecticide and in varying degrees superior to schradan.

It is clear that fluoroacetamide is as effective as the more dangerous sodium fluoroacetate as a systemic insecticide. Whether or not it would be safe for use on food crops remains to be proved. A more detailed report will be published elsewhere.

[7] David, W. A. L., and Gardiner, B. O. C., *Ann. App. Biol.*, **40**, 403 (1953).

It may be of interest to report that we found, as preliminary to many field experiments on the systemic insecticidal activity of fluoroacetamide against aphid pests of a number of flowering plants, that cuttings of rose bushes (unidentified species), infested very seriously with *Macrosiphum rosae* L. and their cut ends dipped in solutions of the insecticide at certain concentration (with 0·05 per cent wetting agent added), gave the kills indicated (Table 1).

Table 1

Dilution	Aphid kill	Phytotoxicity
1 in 1,000	100 per cent in 8 hr.	Some signs
1 in 10,000	100 per cent in 8–10 hr.	Nil
1 in 20,000	100 per cent in 24 hr.	Nil
1 in 100,000	Some kill in 24 hr. (young insects) Complete kill in 72–96 hr.	Nil

The above work was done in the late spring of 1953, and arose from the pioneer work of David and Gardiner[1] on the systemic insecticidal activity of sodium fluoroacetate; later work showed that the insecticide was persistent in the rose bushes for a period of about 2–3 weeks, applied as spray or via root only, at a strength of 1 part in 10,000; that is, aphids occasionally began to reappear after this period of time, necessitating a second spray.

Systemic Insecticides and the Ratio of Green to Dried Hops

In England when hops are picked by hand the work is assessed in terms of the volume of green hops measured as bushels. The green hops are later kiln-dried to about 9 per cent water content before being pressed into bales and sold by weight. Some growers keep a record of the average number of bushels of green hops required each year to give 1 cwt. of dried hops; this average is called the bushel/cwt. ratio. The ratio may vary from year to year on the same farm and from farm to farm in the same year. This variation has been discussed by Glasscock[1], who suggested meteorological conditions at harvesting as one of a number of possible factors concerned.

During recent years it has been reported that the ratio was increasing beyond the limits of normal variability[2]. Data from five East Kent farms (including Wye College) were examined; in three farms the data related to 1942–57 inclusive, and in the other two they related to 1944–57 and 1949–57 respectively. These data are summarized in Table 1, which also gives values for rainfall during August–September of the appropriate years, recorded at Wye College.

Table 1 shows that: (*a*) The average bushel/cwt. ratio for all farms increased from 91 for 1942–49 to 104 for 1950–57; (*b*) the average rainfall during August–September increased from 3·87 to 6·52 in. for the same two eight-year periods. Both these increases are statistically significant at $P = 0{\cdot}01$. The possibility at once suggests itself that the increase in rainfall may have been responsible for the observed increase in the ratio, but this hypothesis is not confirmed by statistical examination of the data. No correlation exists between rainfall and the bushel/cwt. ratio within either of the two periods 1942–49 or 1950–57.

Systemic organo-phosphorus insecticides for control of aphis and red spider were first used commercially on hops in 1949. They have proved most effective and their use has since become general. Of the five farms examined, three introduced systemic insecticides in 1950, one in 1951 and Wye College in 1953; all five farms have since continued to use them. Data for individual farms show that in the years when systemic insecticides were first used the bushel/cwt. ratio rose at once to a level well above the existing average; in three farms it rose to levels greater than previously recorded. It is of significance to note that at Wye College the ratio remained low in the very wet years of 1951 and 1952; when systemic insecticides were introduced in 1953 the ratio rose at once to the high levels at which it has since remained.

Table 1. Data on the Ratio of Bushels of Green Hops harvested per cwt. of Dried Hops for Five Farms in East Kent, and on August–September Rainfall at Wye, Kent, for the Years 1942–57 Inclusive

Year	Bushel/cwt. ratio values for five farms in East Kent					Average ratio for all farms	August–September rainfall (in.)
	Wye College	Farm "E"	Farm "H"	Farm "M"	Farm "W"		
1942	—	109	77	92	—	93	4·53
1943	—	103	88	94	—	95	2·67
1944	—	96	88	86	91	90	4·48
1945	—	98	88	93	100	95	2·83
1946	—	89	87	90	85	88	7·01
1947	—	89	89	91	88	89	0·90
1948	—	99	83	88	85	89	4·47
1949	100	99	86	84	89	92	4·08
	Average 1942–49					91	3·87
1950	100	110*	89*	93	94*	97	4·59
1951	114	112	96	97*	99	104	8·93
1952	103	115	97	97	99	102	8·17
1953	120*	115	92	95	93	103	6·33
1954	127	111	87	96	93	103	5·83
1955	115	110	98	100	107	106	4·71
1956	127	120	88	97	108	108	5·95
1957	125	125	87	105	107	110	7·68
	Average 1950–57					104	6·52

* Year in which systemic insecticides were first used.

It appears probable that the introduction of systemic insecticides has played an appreciable part in increasing the bushel/cwt. ratio. The causes of this increase have not been investigated. A possible explanation is that the superior control of aphis and red spider given by these systemic compounds results in the crop being picked in a more succulent condition than when contact insecticides only were used. It is also possible that the presence of these compounds in the plant may have had physiological side-effects resulting in this increase in the ratio.

This work will be discussed in more detail in the Annual Report of the Department of Hop Research for 1957 which is to be published shortly.

A New Species of *Atolla*

While making a study of the scyphomedusan *Atolla* in north Atlantic waters I recently found that there were two species, *A. wyvillei* and *A. vanhöffeni*[1]. I can now state that there is a third species. Like *A. vanhöffeni*, this is a small species, apparently not exceeding 30 mm. in diameter, but the shape of the base of its stomach is similar to that of *A. wyvillei*.

Whereas *A. vanhöffeni* and *A. wyvillei* have typically 20 and 22 marginal tentacles respectively, this new species has usually 20 or 24 tentacles. It differs also from *A. wyvillei* in that the septa separating the rhopalar and tentacular gastral canals tend to be nearly straight and of uniform thickness, and are almost completely covered to their centripetal ends by the thin part of the coronal muscle. In *A. wyvillei* the septa tend to be club-shaped in appearance, diverging at their ends and extending centripetally beyond the margin of the thin part of the coronal muscle. Its range of coloration appears to be similar to that of *A. wyvillei*.

In view of its small size, I propose to name this species *Atolla parva* n.sp. A fuller description will be given in a later publication, but in the meantime it is hoped that those engaged in studying plankton collections may be able to add to our knowledge of the distribution of the species.

Grain in the Glume of Wheat

In the wheats, as in most grasses, there are empty glumes at the base of each side of the spikelets, and the florets consist of a lemma (flowering glume), palea and flower. In *Triticum vulgare* Host, ten or eleven flower primordia are formed in most spikelets[1] and although in some varieties under good conditions many spikelets carry four or five grains, in most varieties grain is produced only in the two or three basal florets, and the higher florets are undeveloped. The only recorded regular departure from this system is the basal sterility found in some speltoid mutants of *T. vulgare*[2]. In these the lemma of the first floret of most spikelets is empty, and in one mutant both the basal florets are sterile: the initiation of the flower primordia is partially or completely suppressed[3]. One of the more rare abnormalities of flower development in normal varieties is the occurrence of rudimentary florets in the axils of the glumes[3].

Regular development of flower parts in the axil of the second glume has been found in a compactoid wheat. The development varies from the production of a rudimentary palea within the glume to the formation of a complete flower which may set a grain; no increased growth of lodicules[3] has been observed. The 42 ears from five plants grown in the Crop Research Division glasshouse have been examined, and of the 648 well-developed spikelets three, from one plant, were 'normal', 608 showed the abnormality within one glume and 37 showed it in both glumes. Where the order of the florets was noted it was found that the second glume had flower parts in the axil, and where both sides were affected the development in the second glume was the more advanced. Of 222 grains produced by the five plants, 44 were formed in the glumes. In all ears there was incomplete development of the terminal spikelets.

The density of the ears was similar to those of awnless compactoids previously described[4,5], and the appearance of two of the spikelets is shown in Fig. 1. In Fig. 2 the parts of one spikelet are arranged in order. The glumes are long (up to 13 mm.), keeled and fragile, and the shoulder is very narrow; the lemmas and the glumes are awned.

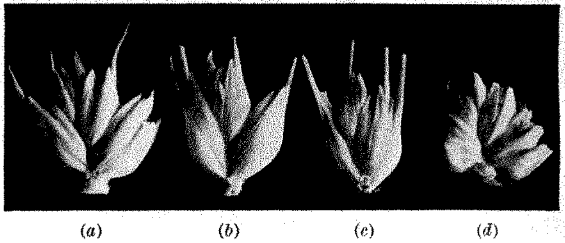

Fig. 1. Spikelets of wheat: (*a*) *T. vulgare* var. Aotea; four grains. (*b*) Compactoid; on left, glume normal, no grain in first flower; grains on right in second flower and in glume. (*c*) Reverse of spikelet from same ear as (*b*); on left, glume with palea, no grain in second flower; grain on right in first flower. (*d*) *T. compactum*, *S*2767; four grains

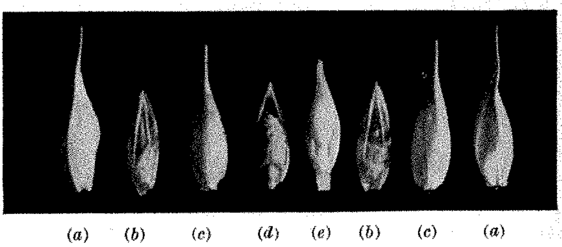

Fig. 2. Spikelet of compactoid, parts in order: (*a*) Glume; (*b*) unfertilized flower; (*c*) lemma; (*d*) grain in second normal floret; (*e*) central florets

The compactoid line is descended from the cross[6] of two awned varieties from the Crop Research Division wheat collection, *S*357 from Crete and *S*1556 from India. The awned progeny of a sub-compactoid F_2 plant consisted of 27 compactoids, 43 sub-compactoids and 32 normal plants, and an F_5 of 42 plants grown from three compactoid F_4's was all compactoid. Chromosomes were counted in root tips of nine of these, including the five discussed above, and all had 44 chromosomes; the material is presumably a stable tetrasome IX compactoid[5].

In the F_3 the abnormality was shown in compactoids, and in the compact part of a sub-compactoid ear, but not in a normal ear. It is thus closely related to compactoidy, and appears, like compactoidy[4], to be independent of the *compactum* factor. It is not found in *T. compactum* Host, and in ears from the F_1 with *T. compactum* (*S*2767) as male parent only the upper spikelets had flower parts in the glumes. It is possible that all compactoids show the character, though some (Mac Key[4], Fig. 53; Sears[5], Fig. 10) do not appear to have fertile glumes. The glumes of another tetrasome compactoid[7] were, apart from being awnless, similar to those of the present material, but their fertility could not be assessed from the photograph (their Fig. 22). A duplication compactoid found recently in unrelated material had relatively short glumes, and no awns; in the one ear harvested most of the 16 spikelets contained two grains, 11 of them had flower parts in the second glume, and in the top third of the head five grains were produced in glumes. It is suspected that the abnormality had not been recorded previously because the effect is not conspicuous unless a grain is formed, and if a grain is formed the impression is given that the glume has been broken off. Both the outer bracts are structurally glumes, and not lemmas.

The production of flower parts in the compactoid glume is an extension of the cytological and phenotypic reciprocality between speltoids, particularly 'sterile base', and compactoids. Awnedness may be of significance[5]; the present material is fully awned, and basal sterility is expressed more fully in awnless speltoids[3], but it is doubtful whether much importance should be attached to simply-inherited characters. Compactoids provide evidence of the genetical characteristics of chromosome IX, part of the *B* genome of wheat, the origin of which is unknown[8], but the normal disomic effects of chromosome IX cannot be predicted, and not until an *Aegilops*, or perhaps an *Agropyron*, with a fertile glume is discovered should any evolutionary significance be attached to this character. (*Added in proof:* Okamoto (*Wheat Inf. Service*, 6, 3; 1957) (E. R. Sears, personal communication) has shown that chromosome IX is in the *A* genome, and has thus reduced the historical importance of speltoidy and compactoidy.)

I wish to thank Mr. E. J. Beuzenberg for the chromosome counts, and Mr. C. J. Miles for the photographs.

Bat Erosion as a Factor in Cave Formation

Observations in three bat-infested caves in Trinidad suggest that roosting bats can play a considerable part in cave excavation where the rock is soft. The best example of this bat erosion is to be seen in a cave in soft coral reef limestone in Mt. Tamana. Wherever the roof is dry, as indicated by the absence of stalactite growth, it is pitted with numerous bell-shaped cavities, the upper parts of which are lined, by day, by a layer of closely packed sleeping bats. On the cave floor below each such cavity is a conical mound of bat guano.

Measurement of these cavities with a pair of long wooden calipers showed depths ranging from 3 ft. to 6 ft. and diameters at the mouth from 1½ ft. to 2½ ft. In the deeper ones measured, the terminal dome and upper part of the shaft were of much the same dimensions as a complete smaller cavity, while the lower part of the shaft widened farther. However, the majority were of irregular shape, having merged with neighbouring cavities.

The bell shape, consisting of a tapered shaft surmounted by a dome, accords with the view that the cavities have been excavated by the claws of generations of roosting bats. Certain species tend to sleep clinging to an overhanging surface and crowded close together, and they can be observed to jostle each other, trying to secure a central position. Such jostling could, over a long period, be expected to erode a cavity in soft granular rock. As the cavity deepened, bats would tend to alight at the lip and climb up the shaft to reach the dome. Thus the lowest and oldest part of the shaft would have been subjected for the longest time to erosion by climbing bats, and could be expected to be of greater diameter than the upper part.

At least nine species of bat have been recorded from these caves, and both total and relative numbers have been observed to vary. Their roosting habits would make an interesting study, but the remoteness of the caves renders such an undertaking difficult.

The Cromer Forest Bed: Preglacial or Interglacial?

The relation of the Cromer Forest Bed Series to the overlying glacial deposits and to the earlier Crag Series has long been a problem, but the recent communication in *Nature* by Prof. P. G. H. Boswell[1] should do much to dispel the idea that the Cromerian stage can be described as an 'Interglacial'. No glacial tills or similar deposits have ever been seen below this Series, and therefore from the point of view of stratigraphy its description as 'Interglacial' can only cause confusion. The very few glacial erratics which have been found in and below the Crag can be attributed to the action of sea-ice, and cannot be counted as representing a 'glaciation'; these erratics are so rare that in practice unfossiliferous Crag deposits can be distinguished in the field from most glacial beds by the fact that erratics are scarcely ever found in the Crag.

As regards conditions during the formation of the Cromer Forest Bed itself, Clement Reid[2] believed that the fossil plants and non-marine shells are in general similar to those now living in Norfolk, with a few exceptions such as *Corbicula fluminalis*. More recently, Woldstedt[3] described a pollen analysis of samples taken from part of the Forest Bed Series as showing a phase with early birch and pine forests succeeded later by a mixed oak association. If work now being done at Cambridge confirms Woldstedt's conclusions, this will suggest that a major climatic fluctuation took place during the formation of the Cromer Forest Bed of a type seen in some interglacial episodes, though differing in detail. This apparent contradiction of a climatic fluctuation which is not preceded by a glacial deposit makes an examination of the marine fauna of the underlying Weybourne Crag most important, in order to find out whether this fauna represents arctic conditions.

In the absence of glacial erratics or actual glacial deposits, it has in fact been argued by Zeuner[4] that the marine fauna of the Weybourne Crag, which underlies the Forest Bed Series, contains sufficient cold indicators to prove glacial conditions before the formation of the Cromer Forest Bed. He considered that an analysis of the marine fauna proves that the cold increased unevenly during Crag times, and that at least two cold episodes represent pre-Cromerian glacial phases; one of his cold episodes is stated to have occurred during the formation of the Weybourne Crag. But Clement Reid[2] showed that only a few cold indicators are known in the Weybourne Crag, and that only one of these (*Astarte borealis*) is at all common, the rest being very rare indeed; in any event a Mediterranean shell is also known to occur (*Astarte incrassata*). Among the marine formations of eastern England it is not the Weybourne Crag which shows the coldest conditions, but the Bridlington Crag of Yorkshire, which is believed to be later than the Cromer Forest Bed[5]. It seems to me that we can conclude that Zeuner's analysis suggests that there may have been fluctuations of climate during Crag times, and these may even go back into the Pliocene, but there is insufficient faunal evidence for calling these fluctuations 'glacials' or 'interglacials'. For similar reasons it is difficult to agree with Woldstedt's use[3] of the term 'Cromer Forest Bed Interglacial'.

As Sainty has pointed out[6], Clement Reid came to the conclusion after several years of work on the Cromer coast that among the occasional marine shells found in the estuarine parts of the Cromer Forest Bed Series, no new 'arrivals' have been recognized as compared with the Weybourne Crag fauna; and in fact the marine fauna of the Weybourne Crag itself only differs from that of the earlier Norwich Crag in the 'arrival' of one new species (*Tellina balthica*) as compared with the Norwich Crag; this species is a common living British shell to-day, and (in spite of its name) is not typical of specially cold conditions. As no new 'arrivals' of cold indicators have yet been found in the Weybourne Crag, there is no proof from the marine fauna that this deposit represents any colder conditions than the Norwich Crag. In view of the lack of geological evidence for truly glacial conditions in the later Crag beds which were formed before the Cromer Forest Bed Series, it seems to me unwise to refer to the Cromer Forest Bed as an 'Interglacial', at least until we know more about conditions during the formation of the Norwich and Weybourne Crags.

"Physics and Metaphysics"

Nature of March 8 contained, over the signature of Prof. L. Rosenfeld, a very lively criticism of the book "Causality and Chance in Modern Physics", published last year by Prof. David Bohm, a book for which I have written the preface. I do not think that the criticisms of Prof. Rosenfeld are justified.

The current probabilistic interpretation of the quantum theory leads in its general lines to exact conclusions. But since it denies every possibility of a precise image of the development of phenomena in space and time, it continues to be surrounded by a certain obscurity. It is not at all certain that it furnishes a complete description of physical reality: scientists as eminent as Planck, Einstein and Schrödinger have always expressed doubts on this subject. The idea of Prof. Bohm that it may be necessary to introduce new 'levels' of physical reality deeper and more hidden than those revealed by current experience therefore seems perfectly defensible to me. For my part, returning after a number of years to certain ideas that I had considered previously when I was developing the first bases of wave mechanics, I have examined this question in the light of the conceptions of Prof. Bohm and in collaboration with certain young scientists at the Institut Henri Poincaré. In particular, I have asked myself whether it would not be possible to find an interpretation which, while retaining all the results given by probabilistic quantum physics, would permit us to obtain a more clear and more intelligible image of microphysical facts. The problem is certainly not an easy one, but I do not believe it to be so impossible as Prof. Rosenfeld thinks; and a certain number of results already obtained in this direction seem encouraging to me.

In any event, no theoretical interpretation can ever be established with a final and complete definitiveness, and for this reason alone it is always permissible to submit those that have already been accepted to a new examination. At the end of the previous century, the great majority of physicists belonged to the 'energeticist' school, which wanted to develop thermodynamics and its related subjects on purely formal bases, and which rejected, often with great disdain, all atomic and corpuscular representations. However, the interpretation of thermodynamics in terms of statistical mechanics, while taking complete account of the success of classical thermodynamics, has permitted us to go very much further. The existence of 'microphysical levels' of atoms and molecules, which the statistical mechanical interpretation of thermodynamics introduces, has been completely and clearly demonstrated. It is not forbidden to think that something analogous could happen again in the years to come. The introduction of a 'sub-quantum' milieu, deeper than the level of current microphysics, could permit the interpretation of the calculations of the present quantum theory in a clearer way, and might lead us further than the current theory can go.

In addition, the quantum theory in its accepted form seems, in a certain measure, to have exhausted its powers of prevision. After a number of years, becoming more and more formal, it has begun to have as many failures as it has successes. Even its proponents themselves seem now to admit the need to make some efforts to modify its bases. In these conditions, it does not seem to me justified to condemn *a priori* the efforts of those who try to take in a new point of view, and to obtain an image of the physical world more intelligible than that based on the conception of complementarity which remains, in spite of everything, rather obscure.

Louis de Broglie

Academie des Sciences,
Paris 1e.

THE impossibility of eliminating the relations of complementarity from atomic physics is not a question of opinion but a simple logical point, as devoid of obscurity, as, for example, the impossibility of defining absolute simultaneity. For a detailed discussion of the points raised in M. de Broglie's comments I may refer the reader to my contribution to the book "Louis de Broglie, Physicien et Penseur" (Paris, 1952), a revised version of which appeared in *Science Progress*, 41, 393 (1953).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURERS, Grade II (honours graduates or associate members of a professional institution), IN MATHEMATICS at Singapore Polytechnic—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (July 3).

SENIOR LECTURER (with a good honours degree or higher degree in chemistry and experience in industry, or teaching and research) IN CHEMISTRY—The Principal, Wigan and District Mining and Technical College, Wigan (July 4).

LECTURER IN THEORETICAL PHYSICS—The Registrar, The University, Manchester 13 (July 5).

RESEARCH ASSISTANT IN THE DEPARTMENT OF PHYSICAL AND INORGANIC CHEMISTRY, to undertake research and to assist with the supervision of Ph.D. students, either (*a*) in the field of physical adsorption; or (*b*) in the field of thermodynamics of solutions—The Registrar, The University, Bristol (July 5).

SENIOR LECTURER (medically qualified and with special qualifications in chemical pathology) IN CHEMICAL PATHOLOGY—The Registrar, The University, Manchester 13 (July 5).

DEMONSTRATOR IN PHYSICAL CHEMISTRY—The Registrar, The University, Hull (July 8).

LECTURER IN GEOLOGY—The Registrar (Room 22, O.R.B.), The University, Reading (July 12).

RESEARCH ASSISTANT (preferably with a good knowledge of biology and physical sciences) IN THE DEPARTMENT OF ANATOMY, for work mainly connected with electron microscopy—The Secretary, University College, Gower Street, London, W.C.1 (July 12).

RESEARCH ASSISTANT (with a good degree and preferably research experience in botany or biochemistry) IN THE DEPARTMENT OF BOTANY, to work on biochemical physiology—The Secretary, University College, Gower Street, London, W.C.1 (July 14).

ASSISTANT EXPERIMENTAL OFFICER (graduate) IN THE BEE DEPARTMENT, for work on field behaviour of bees—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (July 15).

LECTURER (with special experience in plant physiology) IN BOTANY—The Registrar, The University, Birmingham (July 15).

VOKES RESEARCH FELLOW IN THE DEPARTMENT OF MECHANICAL ENGINEERING, to undertake research in the field of filtration, the separation of mixtures, or allied problems in fluid mechanics—The Registrar, The University, Southampton (July 15).

DEMONSTRATOR IN THE DEPARTMENT OF GEOGRAPHY—The Secretary of the Appointments Committee, Department of Geography, The University, Downing Place, Cambridge (July 16).

RESEARCH WORKER (with a university degree, preferably in forestry, and some practical forestry and research experience), to continue the special study of shelterbelt problems in Scotland by the Department of Forestry—The Secretary, The University, Edinburgh (July 18).

RESEARCH ASSISTANT (graduate in zoology or candidate for honours this year) IN ZOOLOGY, to work on the biology of fish populations in the River Thames—The Registrar (Room 22, O.R.B.), The University, Reading (July 19).

ASSISTANT LECTURER or LECTURER IN CHEMISTRY—The Secretary, Royal College of Science and Technology, Glasgow (July 21).

SENIOR LECTURER IN BIOCHEMISTRY at the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, July 21).

LECTURER IN THE DEPARTMENT OF PHYSIOLOGICAL CHEMISTRY—The Registrar (Room 22, O.R.B.), The University, Reading (July 31).

LECTURER or SENIOR LECTURER IN PATHOLOGY in the Faculty of Rural Science, University of New England, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (July 31).

LECTURER (preferably with special qualifications in applied mathematics) IN MATHEMATICS at the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, July 31).

LECTURER (with an honours degree in zoology and preferably familiar with vertebrate zoology and an interest in the ecology of mammals) IN THE DEPARTMENT OF ZOOLOGY at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, July 31).

LECTURER IN SOCIAL ANTHROPOLOGY at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 10).

CHAIR OF BOTANY in the University College of Ghana—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 15).

LECTURER or SENIOR LECTURER IN POULTRY SCIENCE in the Faculty of Rural Science, University of New England, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (August 31).

CHEMIST (with an honours degree in chemistry or equivalent professional qualification plus a minimum of three years post-qualification experience) IN THE MEDICAL DEPARTMENT, Hong Kong, for general analytical and supervisory work—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.117/51/018/T.

LECTURER (with experience in rock and mineral analysis) IN THE PURE GEOCHEMISTRY SECTION OF THE GEOLOGY DEPARTMENT, for duties which will include teaching petrology and research in pure geochemistry or chemical petrology—Professor D. Williams, Geology Department, Imperial College, London, S.W.7.

PROFESSOR (familiar with gas turbines, jet propulsion and internal combustion engines) OF THERMODYNAMICS, for duties which will include lecturing to undergraduate and postgraduate students and the direction of research—The Dean of Engineering, Ecole Polytechnique (Canadian University), 1430 St. Denis Street, Montreal, Canada.

RESEARCH ASSISTANT IN THE CRYSTALLOGRAPHIC LABORATORY, for structure analysis of organo-metallic compounds—Secretary of the University of Cambridge, Department of Physics, Cavendish Laboratory, Free School Lane, Cambridge.

RESEARCH ASSISTANTS, IN THE DEPARTMENTS OF BOTANY AND ZOOLOGY, CHEMISTRY, MATHEMATICS, METALLURGY AND PHYSICS—The Secretary, Sir John Cass College, Jewry Street, London, E.C.1.

SCIENTIFIC ASSISTANT (with a good science degree, a reading knowledge of two European languages (preferably other than French or German), ability to write good English, and preferably a knowledge of soil science and plant physiology), for work in a scientific information service involving abstracting and indexing—The Director, Rothamsted Experimental Station (Commonwealth Bureau of Soils), Harpenden, Herts.

SCIENTIST (with a first- or second-class honours degree in physics, physical chemistry or mathematics as a principal subject, and preferably with some previous experience in airborne dust measurement), for research on methods of assessing the dust content of the atmosphere, and the investigation of airborne dust conditions in mines, involving some underground work—Divisional Chief Staff Officer, National Coal Board, East Midlands Division, Sherwood Lodge, Arnold, Nottingham, quoting S.V.851.

SENIOR LECTURER (highly qualified in mathematics, considerable teaching and/or industrial experience, and preferably the ability to organize special courses in mathematics for highly qualified students in industry) IN MATHEMATICS—The Clerk to the Governors, South-East Essex Technical College, Longbridge Road, Dagenham.

RESEARCH PHYSICIST
ph Lucas (Electrical) Limited require a Re-
Physicist to work in the Company's Labora-
Marston Green. The post will carry the
f Research Officer, and an honours degree
sics is required with either a higher degree
ne experience of research. The post is
ent and pensionable. Salary according to
ations and experience.
ly, in writing, giving full details, to the
nel Manager, Joseph Lucas (Electrical)
, Great King Street, Birmingham 19, quot-
erence PM/D/222.

ANIC CHEMIST. THE PYRETHRUM
of Kenya require an organic chemist for
aboratories at Nakuru. It would be pre-
to appoint a man with a good honours
and M.Sc. or Ph.D. or equivalent, age
5, who has had several years' experience of
c organic chemistry. A knowledge of
ing and wetting agents and preferably
perience in the formulation of insecticides
rmaceuticals or cosmetics would also be
Five-year contract initially; three weeks'
local leave and two months' overseas study
fter two and a half years' service, and two
overseas terminal leave on completion of
t. Nakuru is in the White Highlands at an
of 6,500 ft. and the climate is pleasant
nperate. Return air fare paid up to three
passages. Initial salary £1,250 to £1,500
ng to experience with £50 annual incre-
together with superannuation or provident
ntributions. Hard furnished house or flat
e at a rental of not more than 15 per cent
y.—Send full details to African Pyrethrum
al Information Centre Ltd., 4 Grafton
London, W.1.

COOPER TECHNICAL BUREAU (THE
h Organization of Cooper McDougall and
on Ltd.) requires a young male graduate
nistry, with or without experience. The
s concerned with the development of
s in collaboration with biological colleagues
r laboratories in the organization. This is
ellent opportunity for a young man with
e. Salary according to age, qualifications
perience.—For form of application apply
Director, Cooper Technical Bureau,
msted.

JOSEPH LUCAS
(ELECTRICAL) LIMITED

ENGINEERS & PHYSICISTS

As a result of expansion of our road vehicle lighting development department to meet the growing demands of the motor industry we have vacancies for engineers and physicists of at least higher national certificate standard to work on the following projects. Experience or knowledge of photometric and electrical instruments is desirable.

The design and development of vehicle lighting equipment, and in particular the development of optical systems for future products.

Development work on specific problems related to vehicle lighting equipment and the design of laboratory and factory control equipment for these products.

These positions carry attractive starting salaries and provide excellent prospects for advancement. Staff Pension Fund.

Apply, in writing, giving full details of age, qualifications and experience, to the Personnel Manager, JOSEPH LUCAS (ELECTRICAL) LIMITED, Great King Street, Birmingham, 19, quoting reference PM/D/231.

THE COOPER TECHNICAL BUREAU (THE Research Organization of Cooper McDougall and Robertson Ltd.) requires a young graduate with an interest in livestock parasitology for laboratory and field development work in applied helminthology and entomology. Salary according to age, qualifications and experience.—For form of application apply The Director, Cooper Technical Bureau, Berkhamsted.

GRANTS & SCHOLARSHIPS

LISTER INSTITUTE OF PREVENTIVE MEDICINE

A Research Studentship (value £400 per annum free of tax) is available for an honours graduate in biochemistry, or chemistry, wishing to study for a Ph.D. degree. The work will be of a physico-chemical nature and will be related to the fractionation of human plasma proteins, especially those concerned in the clotting mechanism. The successful candidate will be expected to take up the work in September or October.

Applications, stating qualifications, should be sent to the Secretary, Lister Institute, Chelsea Bridge Road, London, S.W.1.

TRADE ANNOUNCEMENTS

THE PRICE OF SAFETY IS THE COST OF a JENCONS interchangeable desiccator.—Send for price and spares list to Jencons (Scientific) Ltd., Mark Road, Hemel Hempstead, Herts.

HIGH VACUUM STOPCOCKS DISPATCHED by return from our varied stock of over 10,000. Catalogue on request.—G. Springham and Co., Harlow, Essex (Tel. Harlow 24108).

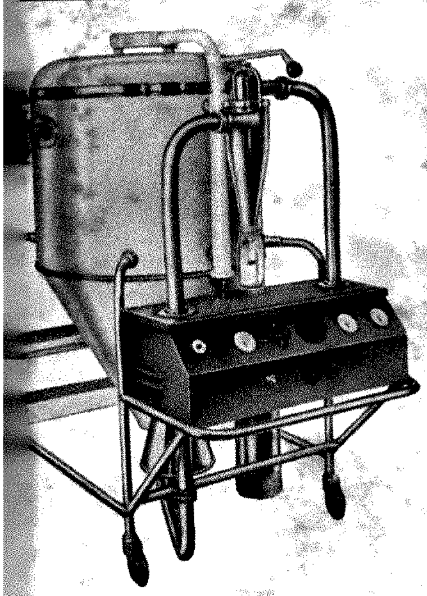
MISCELLANEOUS

MURDOCH TRUST

For the BENEFIT of INDIGENT BACHELORS and WIDOWERS of good character, over 55 years of age, who have done " something " in the way of promoting or helping some branch of Science.

Donations or pensions may be granted to persons who comply with these conditions.

For particulars, apply to MESSRS. SHEPHERD & WEDDERBURN, W.S., 16 Charlotte Square, Edinburgh, 2.



SPRAY DRYERS

—backed by 25 years' experience

For production of animal, vegetable and chemical products of all kinds.

350 industrial and 220 laboratory N.A. Spray Dryers are in operation throughout the world.

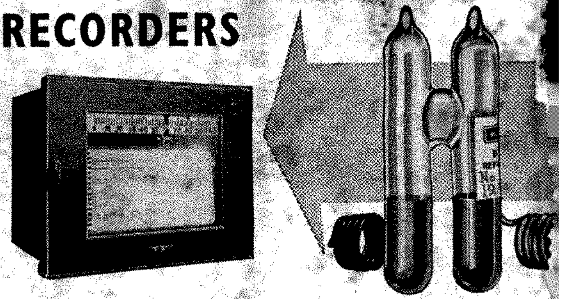
MUIRHEAD D-845 CELLS FC RECORDERS



These cells will function under widely varying temperatu conditions—be tolerant to a wide range of mounting positi —withstand rough handling and yet maintain an accu and stable reference voltage. Mounted and unmounted ty are available from stock.

E.M.F. 1·0193 volts absolute, subject to manufactur tolerance of 0·0005 V Unmounted, 0·0002 V Mounted.
Temperature coefficient Does not exceed 5μV/°C o the range 10°—40° C.
Temperature hysteresis Negligible over the norn temperature range.
Internal resistance at 25° C. Average 800 ohn maximum 1200 ohms.
